6. Sixteen deaths from plague, or suspected plague, were reported in Rajputana. All of these were imported cases, and were mostly passengers taken out of trains. An interesting account is given in the report of the outbreak of plague which took place in 1836 and 1837 in Marwar Pali. Although in 1896 the disease was imported by persons coming from infected localities, it did not spread to the people of Rajputana. What share the measures of quarantine, segregation, and disinfection had in preventing the spread of the disease may be a matter of opinion. The Administrative Medical Officer writes:—"The season was greatly against the spread of plague in "Rajputana; the monsoon rains were over early, the winter rains were unusually light, and the "country was in consequence exceedingly dry; the hot weather also began earlier, and the heat was "more intense than usual, so all these conditions were unfavourable for the multiplication of the "plague germ, and the spread of plague among the people."

7. *Sanitation.*—The remarks under this heading show that, as regards one of the first essentials of healthy life, the inhabitants of most of the larger towns in Rajputana are not badly off: the water-supply of the majority of them is described as being "abundant and good." There are, however, exceptions. The water-supply of the city of Bhurtpore, with a population of 68,033, is bad; but it is proposed to give an improved supply to the city and suburbs as soon as funds become available. Dr. Adams says:—"Undoubted and steady progress is being made in sanitation in "Rajputana, especially in some of the capitals and large towns, in many of which it is now "beginning to be pretty generally recognized that an observance of the laws of health materially "benefits the community at large." He adds that village sanitation, although still very backward, is year by year receiving more attention; and urges on the Residency and Agency Surgeons the necessity for their taking an active personal share in the endeavour to introduce sanitary reform, instead of leaving this important duty to their subordinates, "if they intend village sanitation to "become anything more than a mere heading for their annual reports."

8. Under the heading "Dispensaries" an account is given of the progress being made in building new hospitals and dispensaries, and in improving old ones. The Administrative Medical Officer considers that "progress in this direction is very satisfactory."

9. The health of the only *jail* of the Ajmere Division was satisfactory. The death-rate, which was 45·35 in 1895 fell to 13·26 per mille in the year under report; whilst the admissions into hospital fell from 285 to only 69. In the jails of the Native States the mortality was much the same in both years, having been 28·17 in 1896 as compared with 28·09 during the preceding year. The admissions into hospital from malarial fevers and spleen diseases in the Ajmere jail fell from 74 per cent. of all the admissions in the preceding year to 19 per cent.; and in the Native States jails from 33 to 21 per cent. These favourable results were doubtless in great part due to the exceptional dryness of the year. It is suggestive of the hygienic conditions prevailing in the Ajmere as compared with the Native States jails that, whilst in the former 9 per cent. of the admissions and no deaths were due to dysentery, in the latter 14 per cent. of the admissions and 33 per cent. of all the deaths were due to that disease. Prevalence of dysentery in a jail may generally be taken as an indication that the hygienic conditions of that jail are unsatisfactory. Although in several of the Native States much is being done by improving the ventilation of the buildings, increasing the scale of diet, and other measures to ameliorate the condition of the prisoners, an examination of the brief accounts given of the jails shows that the state of many of them is such as to be a reproach to those responsible for its continuance, and a cruel injustice to those confined in them. The worst of these, the Banswara jail, may be taken as an example. We drew attention to the state of this jail in our memorandum for 1894, yet we have the following description of it in 1896:—"This jail is always unhealthy, badly "managed, and overcrowded; its site is bad, and also its construction, as I pointed out when it was "being added to some years ago. The death-rate rose from 62·07 in 1895 to the enormous mortality "of 131·60 in the year under report; but the admissions fell from 3,145·04 to 2,747·16 per mille." The condition of some of the other jails is little better. Of that of Partabgarh the Administrative Medical Officer writes:—"This jail is mostly very much overcrowded; it is badly drained, and "unsuited for a prison;" and of that of Shahpura:—"This jail has been very unhealthy throughout "the year, and it is generally much overcrowded. The mortality has gone up from 47·25 to 67·23, "and the admissions have risen from 2,244·8 to 2,386·55 per mille." It must be evident from these descriptions that, although "great progress has, during recent years, been made in jail management "in the Native States of Rajputana, and many of the jails are now in good order," the need for reform in others is urgent.

10. Briefly, the year 1896 was characterised by scanty or unseasonable rainfall, resulting in scarcity of water, deficient harvests, and high prices. Owing to the early cessation of the rains in the end of August or beginning of September, the last months of the year were exceptionally dry, and, as a consequence, unusually free from diseases of malarial origin. Registration is still very backward in the Native States, and the returns of births and deaths unreliable. In Ajmere-Merwara, in which registration is comparatively accurate, the birth-rate decreased whilst the death-rate increased, the former result being probably due to the hard times which prevailed during the preceding year, and the latter to the privations caused by crop failure and high prices in 1896. Cholera prevailed in severe epidemic form in some of the Native States, especially in Marwar; and small-pox was accountable for a ratio of 7·03 deaths in the Ajmere Division. The ratio of success recorded in primary vaccination continues to be phenomenally high in a number of the Native States, suggesting the need for vigilance on the part of inspecting officers. Plague was imported into Rajputana, and 16 deaths from plague, or suspected plague, were reported. The disease did not, however, spread to the inhabitants of the country, but was confined to travellers from infected localities outside the province. Progress in sanitation is being made in the Native States, more especially in some of the capitals and large towns. Improvement of the jails of most of the Native States is also being effected, but in some, owing to the lamentably defective sanitary conditions still prevailing in them, the death-rate continues to be excessive.

No. 9.

Memorandum by the Army Sanitary Commission on the Medical and Sanitary Report of Coorg for 1896.

1. Of this Report the Chief Commissioner truly observes that "the remarks are almost entirely "confined to a bald repetition of the contents of the statements." Little attempt is made to explain variations and anomalies in the statistics. As compared with other provinces Coorg is insignificant in its extent and population, the latter numbering only 173,055; but an examination of the causes which render its vital statistics exceptional would not on that account necessarily be devoid of interest or usefulness.

2. Coorg did not suffer from the deficient rainfall which brought disaster to most other provinces of India during the year: the 157·63 inches recorded exceed the average of the previous 13 years. There was no unusual scarcity of food supplies, and prices did not greatly differ from the average of the quinquennial period 1891–95. The influence of these conditions on the public health, as gathered from the statement given in paragraph 3 of the Report, does not appear to have been adverse. Except in December, when it is said to have been "indifferent," the public health during each of the other 11 months is described as having been "fair."

3. *Vital Statistics.*—In the previous year, and generally during the previous 10 years for which statistics are given, the number of deaths exceeded the number of births, but in 1896 there was a small excess of 32 births over deaths. The excess of deaths over births hitherto recorded has been regarded as due to the influx into Coorg of large numbers of coolies who come to work on the coffee estates, and who do not bring their wives with them. Doubtless this is one of the causes which has contributed to bring about the excess of deaths, but other peculiarities in the vital statistics of Coorg lead to the suspicion that defective registration may also be concerned in bringing about this result. According to Annual Form No. I., the proportion of the sexes born is 97·68 male to every 100 female children. If these figures represent the actual proportion, Coorg differs from the rest of India in having more female than male children born in it. In the report it is stated that of 160 deaths which occurred in Mercara town, 45 were coolies from Mysore, Malabar and other places, and were not inhabitants of Mercara. To ascertain the real mortality among residents, these 45 deaths, it is said, should be deducted, when the death-rate of the town would be found to be, not 22·75, but only 16·35 per thousand of population. Needless to say, a death-rate of only 16·35 would be an incredible one in Mercara. Again, although the returns show that only 97·68 male children were born to every 100 female children, the deaths of 123·01 males to every 100 females are recorded. The explanation of this excess of deaths of males is doubtless the same as that given to account for the disproportionately small number of births as compared with deaths, viz., the influx into Coorg of a large number of coolies without their wives. As the Chief Commissioner remarks, it is not easy to understand why the deaths should so largely exceed the births in the two largest towns, especially in Mercara, where sanitation is presumably attended to, and where there is a supply of good drinking water, or why during the past two years the number of births should have decreased so considerably. Defective registration will probably be found to be to some extent accountable for these anomalies and variations. The scattered nature of the dwellings of the people renders accurate registration unusually difficult; and it is gathered from the account given of the agencies entrusted with the record of births and deaths that their efficiency is more than doubtful.

4. *Chief Diseases.*—*Cholera* accounted for 49 deaths, giving a ratio per thousand of population of 0·28 as compared with a mean of only 0·09 for the previous five years. *Small-pox* deaths numbered 18. An examination of the record of small-pox mortality shows that the disease prevails in Coorg periodically in severe and fatal epidemic form. In 1892 the ratio of deaths from small-pox was 5·27, and judging from the large proportion of the infant population which annually escapes

vaccination, the recurrence of a similar epidemic is far from unlikely. During the year 1896, according to the returns, there were 4,606 children born: of these 1,061 died, leaving available for vaccination 3,545. Of this last number 1,289 were successfully vaccinated, leaving no fewer than 2,356 unprotected against small-pox. The recorded percentage of success in primary vaccination was 92·02, and in re-vaccination 82·95. It is hard to believe that so high a percentage of success was obtained in re-vaccination. In Coorg, animal lymph is exclusively used in vaccination.

5. As usual, *fever* was credited with the largest number of deaths. The ratio of deaths attributed to this cause was 20·53 per thousand of population as compared with 23·48 in 1895, and with a mean of 19·66 during the previous five years. The total death-rate for the province having been 26·43, if the ratio due to fever be deducted, only 5·90 remains to be credited to all other diseases. "It is "perhaps, unsafe to generalize from the figures of one year," writes the Chief Commissoner, "but "the diminution of fever, which is the main disease of Coorg, seems to show that this ailment has no "necessary connection either with an abundant rainfall, or with a rise in the price of *ragi*, which is "probably in some parts of Coorg the staple food of the country." With a view to alleviate the effects of fever, the sale at post offices of quinine powders in 5-grain packets was introduced in January in places where there were no dispensaries. It is added that, "an endeavour was made to "ascertain the number of packets sold at each post office, but without avail." The reply received from the Postmaster-General of Madras to a request for this information is worth placing on record. "It is one of the principles and conditions of the system under which post offices sell quinine, that "they do not keep or render any accounts of quinine sales or stocks." Under such conditions, which are probably peculiar to Madras, there may not unnaturally be some hesitation in entrusting quinine to post offices for sale.

6. *Sanitary Works.*—No permanent work of importance was executed during the year. An estimate was made for providing the town of Virajendrapet with a good water-supply; but the cost was found to be almost prohibitive. In paragraph 7 of our last year's memorandum we referred to the steps being taken to build shelters for the use of coolies entering and leaving the province. It is satisfactory to learn that the building of these is being energetically proceeded with, and that they were expected to be ready for occupation before the bursting of the monsoon of 1897. The mortality amongst these coolies has hitherto been excessive and has been suggested as the chief cause of the high death-rate of the province. Regarding the introduction into selected villages of a system of village sanitary inspection, in accordance with the instructions issued by the Government of India, "the information given in the reports is meagre," and the Chief Commissioner requests that the Civil Surgeon will bear the point in mind and deal with it more fully in future reports.

7. *Summary.*—The year was characterized by a rainfall above the average. There was little alteration from ordinary in the price of grain. The number of births was slightly in excess of the number of deaths: hitherto the latter have usually been the more numerous. There are peculiarities in the vital statistics recorded in this little province which need explanation. The records are exceptional in showing a death-rate generally in excess of the birth-rate, and the number of female to be in excess of the number of male children annually born. Fever, as usual, was accountable for the greater part of the mortality. Although more numerous than during the preceding year, the deaths from cholera and small-pox were not excessive. The returns of vaccination show serious neglect of infant vaccination. The erection on the principal *ghaut* roads of shelters for the coolies entering and leaving Coorg is being vigorously proceeded with. A scheme for providing the second of the two chief towns of the province with a good supply of drinking water has to stand over for the present owing to want of a sufficiency of funds. In next report an endeavour might be made to explain some of the more striking anomalies and variations noticed in the vital statistics of the province.

12th October, 1898.

No. 10.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Madras for 1896.

For the sake of brevity the form of heading hitherto used in dealing with the Report of the Sanitary Commissioner of Madras has been adhered to; but the title of the volume containing the report has undergone considerable alteration: it is now "The First Annual Report of the Sanitary "Board, the Thirty-third Annual Report of the Sanitary Commissioner, and the Seventh Report of "the Sanitary Engineer, Madras, 1896." It is stated that towards the end of the year the Sanitary Board was reconstituted. It now consists of three members, the Chief Engineer, Public Works Department, the Surgeon-General with the Government of Madras, and a member of the Indian Civil Service. The Chief Engineer is President, and the chief assistant of his office Secretary of the Board. A copy of the rules for conducting the business of this Board is given. From these rules it appears that no sanitary work estimated to cost more than Rs. 200, shall be undertaken by any local board or municipal council without the prior approval of the Sanitary Board. The initiation of sanitary works of any importance will thus require the sanction of the Board. Rule 14 describes the procedure to be adopted in dealing with a major sanitary scheme. In the first place, the Sanitary Commissioner will bring to the notice of the Board the need for such a scheme: the Board will then call on the Sanitary Engineer to report how the scheme can best be carried out: the Engineer's report will be sent to the Sanitary Commissioner for his opinion from a sanitary point of view: should the latter condemn the Sanitary Engineer's scheme, the Board will decide whether the Sanitary Engineer should be required

to modify his proposals, or whether the matter should be at once referred for the orders of Government as to the preparation of detailed plans and estimates. With such a system of check there should be little danger of insufficiently considered schemes of sanitary improvement being hastily undertaken in Madras. The report of the Board for 1896 is commendably short. It is contained in less than three pages, and is followed by an appendix of other three pages giving a list of the schemes dealt with by, and a statement giving particulars of works referred to, the Sanitary Board for scrutiny.

2. The Sanitary Commissioner's Report, which is submitted to Government by the Sanitary Board, opens with a section on the year's rainfall. The Madras Presidency was no exception to the rest of India in the irregular and unseasonable nature of its rainfall during 1896. Although the northern districts of the east coast received their normal amount of rain during the south-west monsoon, in three out of four of them the north-east monsoon of the last three months of the year was a failure. Likewise in the Deccan districts, which lie within the so-called "famine zone," both monsoons were scanty, the north-east monsoon being practically a failure. The consequences of this insufficient and irregularly distributed rainfall were serious. Failure of crops and of fodder followed, causing much suffering to man and beast. The Sanitary Commissioner, however, shows that crop failure was not the sole cause of the distress; high prices, due to active export of grain to Bombay and the North-Western Provinces, in which famine prevailed, contributed largely to scarcity and privation in Madras.

3. *Vital Statistics.*—In spite of the efforts to improve it, registration of births and deaths is still very defective. During the year "a circular was issued to all municipalities directing their attention "to the importance, from a sanitary, economical, and medico-legal point of view, of insisting on "prompt registration." This exhortation, the Sanitary Commissioner believes, had a satisfactory influence. The statement given at page 23 of the report shows that, in the case of 543 births and 407 deaths which failed to be registered in municipalities, prosecutions followed. This is perhaps the most effectual form of exhortation where neglect of registration persists from year to year. The Governor of Madras, in reviewing the report, writes:—"The system of registration continued "the same as in the previous year, but in its Order No. 476 (Revenue), dated 21st September 1896, "the Government decided to take steps for its improvement:—

"(1.) By placing the village establishments in the zamindari tracts under adequate control;

"(2.) By initiating legislation with the object of making registration in more advanced areas "compulsory by law; and

"(3.) By gradually transferring the duty of conducting registration in rural areas from the "overworked village accountant to the village headman."

It is not clear how the first of these steps will operate in improving registration. With regard to the second, it seems late in the day to restrict the improvement of registration to limited areas. Of the influence which the last of the steps mentioned will exercise, it will probably only be possible to judge after the change has had effect for some time. Meanwhile, Madras records a birth-rate for 1896 of 29·9, and a death-rate of 20·6, per mille of population. It may serve as some indication of the state of registration in the Madras Presidency if we compare its birth and death ratios for 1896 with those recorded in the neighbouring Provinces of Bengal, Bombay, and the Central Provinces for the same year:—

	Births.	Deaths.
Bengal	38·03	34·17
Bombay	36·76	31·69
Central Provinces	31·68	49·31
Madras	29·9	20·6

In all of the Provinces mentioned scarcity and famine prevailed, so that the conditions influencing at least the death-rates in all of them were more or less similar. It is impossible to believe that in a year during which scarcity, deepening into famine, afflicted the Madras Presidency over a considerable part of its area, 20·6 can represent even approximately the ratio of deaths per thousand of its population. The comparison of its record of vital statistics with the record given by its neighbours—and the latter is doubtless far from perfect—will afford some measure of the incompleteness of registration still prevailing in Madras. It is in rural areas that registration is most defective. In the 57 municipalities the birth-rate for the year under report was 36·1, and the death-rate 30·7 per mille of population: in rural areas the recorded birth-rate for the same year was 26·7 and the recorded death-rate 18·4. The district of Malabar, with a population of 2,636,674, records a birth-rate of only 22·5 and a death-rate of 15·7. It would not perhaps be an exaggeration to estimate the actual number of births and deaths in this district at twice the number registered.

4. *Chief Diseases.*—Cholera prevailed in every district of the Presidency and caused a total of 47,847 deaths during the year, or more than twice the number ascribed to it in the preceding year. As usual, its severity varied greatly in different places and at different times. Whilst in South Canara only 13 persons died from it, in Coimbatore 10,731 deaths are recorded as due to it. So with regard to the season of the year when it was most prevalent, taking the Presidency as a whole, 17,999 deaths are recorded against it in December and only 272 in March. The Sanitary Commissioner gives

a table showing the incidence of the disease according to monsoon periods; but cholera refuses to accommodate its incidence to any law which has yet been discovered. If the district of Bellary is selected from Statement No. VII., Appendix D, it will be seen that its course during the year resembled that common in the more Northern Provinces of India. The three first months and the two last months of the year were those of least cholera mortality; whilst the greatest number of deaths took place in May, June, and July. On the other hand, not a single death was recorded in Coimbatore during the first six months of the year; whilst September and December were the months of greatest cholera mortality. The partial nature of its incidence is as characteristic in Madras as in other parts of India. Although it prevailed in every district of the Presidency, in only 4,390 villages of a total of 44,678 did cases occur, or in about one in every ten. A satisfactory explanation of the reason why the nine villages escaped and the one was attacked is still wanting. In point of their sanitary or insanitary condition there is probably little distinguishable difference between those that suffered and those that escaped. Such sanitary improvements as have been effected in towns have not, so far, placed them in a better position for warding off cholera than villages in which things remain pretty much what they have been from times immemorial. "The "mortality in municipalities from this disease was at the rate of 2·1 per mille of population," as compared with a rate of 1·3 for the Presidency as a whole. Unfortunately, the most effectual of all the hitherto discovered methods of dealing with a cholera epidemic cannot readily be applied to cities and towns. Prompt evacuation of the affected locality, when such prompt evacuation is practicable and properly carried out, has scarcely ever been known to fail in cutting short an outbreak of the disease. Year after year the efficiency of this method is demonstrated in the case of our troops and jail population. The same remedy applies to plague. In the case of neither disease has a remedy been found so successful as the prompt and thorough abandonment for a time of the affected locality. But prevention is better than cure; and perhaps there are few who doubt that in sanitation thoroughly carried out in every detail this prevention will ultimately be found.

5. *Small-pox* was accountable for 9,410 deaths. The returns show that no district enjoyed entire immunity from the disease. Of the total number of deaths, 2,245 occurred amongst infants under one year, and 3,632 amongst children between one and 12 years of age. In some towns, such as Vellore and Gudiyattam, the death-rate was very high, having been 5·3 in the former and 2·1 in the latter. It is evident from these figures that, as stated in the review of the report, compulsory vaccination is not being strictly enforced in these towns. During the year 1896–97 there was an increase of 49,549 cases of vaccination. Primary vaccine operations increased by 52,506; whilst re-vaccination operations decreased by 2,957. The ratio per cent. of total successful cases, according to the statement given in paragraph 9 of the Vaccination Report for 1896–97, is 92·5 in primary vaccination and 80·3 in re-vaccination, showing a slight falling-off as compared with the ratios for the preceding year. This, however, the Inspector of Vaccination thinks is not "to be deplored, as it "probably points to greater accuracy in the returns." Although the returns of vaccination in the Madras Presidency are now being subjected to special scrutiny with a view to preventing a continuance of their falsification, it is evident that the Inspector is not yet satisfied with their accuracy or with the sufficiency of the means at his disposal for the detection and prevention of fraud. He suggests the appointment of two Assistant Inspectors of the Assistant Surgeon class, "whose duty it would be to inspect the verification work of the deputies, and so impose a wholesome "restraint on the dishonest practices which at present prevail to too large an extent in the "department." He adds, that the expected improvement as regards the accuracy of the returns submitted would enable one in future to "get an idea of the actual extent to which the population is "really protected, which is impossible at present." Perhaps, if the Civil Surgeons were to have charge of, and were held responsible for, the work of vaccination in their districts, the improvement of the accuracy of the returns might be effected without the need for appointing extra inspectors. During the year, the number of children under one year of age vaccinated was equal to 33·6 per cent., or one-third of the total number of registered births. From these figures it is evident that, until a very large increase in this proportion comes to be effected, small-pox will not die out from want of susceptible material to keep it alive. In some of the districts the proportion of infants protected by vaccination is altogether insignificant. In the vast district of Malabar, with its population of upwards of two and a half millions, only 1·4 per cent. of the children under one year of age were successfully vaccinated. "Fresh calf vaccine shows, as usual, the greatest percentage of success, "viz., 97·2; then comes vaccine sent out in glass without any preservative; then lanaline paste; and "lastly glycerine with 94·6, 94, and 88·9 respectively." But until the department has been purified from the fraudulent practices which have hitherto prevailed and, according to the Inspector, still prevail in the preparation of its returns, too much weight need not be given to these or to any of the other figures supplied.

6. *Fevers* were less fatal than during the preceding year, but the ratio of deaths per mille of population recorded to have been due to them was slightly higher than the mean ratio for the previous five years. An examination of Table IX. in Appendix D. shows that, as Dr. King remarks, "the incidence of fever on the population varies but slightly, from year to year." The shortness of the rainfall, which resulted in crop failure and scarcity in the Deccan districts, was no doubt at the same time the cause of a sensible decrease in the prevalence of malarial fevers in three out of the four of those districts. Increased mortality, which almost invariably accompanies or follows privation due to scarcity, seems thus to have been to some extent compensated for by decreased mortality arising from the cause which brought about the scarcity. Regarding the increase of mortality from fever in the town of Karúr, the Sanitary Commissioner writes:—"In this case "the sub-soil of the town is saturated with soakage from cesspools, and as typhoid is a recognised "disease in this town, it need not be assumed that solely malarial fever was dealt with."

7. *Sanitary Works.*—Progress is being made in the direction of providing the larger towns with water-supplies. "Four water-supply works were in progress during the year. Of these, the "Trinchinopoly and Dindigul works were completed and handed over to the Municipal Councils "concerned, and fair progress was made in carrying out the schemes for the water-supply of Kurnool

" and Conjeeveram." In addition " nine surveys were completed and five water-supply schemes were " prepared and submitted to the Sanitary Board during the year, while the estimates for five other " water-supply schemes underwent revision." Excluding the city of Madras, which has a separate sanitary report for itself, the estimated income of the other municipalities of the Presidency for 1896–97 was just over thirty-three and a quarter lakhs of rupees ; and of this amount close upon half, or 48·1 per cent., was allotted for sanitary purposes. Of the sum so alloted, over four lakhs were expended on conservancy, nearly three lakhs on improvement of water-supply, and close on two lakhs in improving village sites. From this it will appear that the main want is the want of money for improving the sanitary state of the towns of Madras as of the other towns of India. The funds available for sanitary purposes in the Madras Municipalities are obviously out of all proportion insignificant in amount, when the requirements of the municipalities are taken into account. As Dr. King remarks :—" It cannot be said that the rate of sanitary progress in municipalities is such as " to render the sanitarian sanguine, still progress is apparent, and, this being so, it may be assumed " that reforms will be introduced in an ever-increasing ratio as one improvement is almost necessarily " followed by another with the object of securing full results."

8. A table is given at page 46 of the report, showing the effect of public water and sewerage works in the case of the nine towns already provided with water-supplies. In only three of these towns are drainage works completed. A comparison of the death-rates recorded before, with those recorded after, the completion of these works constrains the Sanitary Commissioner to admit that the results acquired so far are not striking. He adds :—" No other than a mediocre result from sanitary works " in this Presidency can, however, be expected, so long as they are not constructed so as to involve " not the major portion of towns, but the whole, so long as the facilities afforded are not such as to " permit free use of the water by the inhabitants in all parts of the town and at all times of the day ; " and, above all, so long as the municipal councils persist in retaining the old wells and tanks which " the public water-supplies should have replaced."

9. On sanitary works carried out by district boards, an account is given of the sums expended in the table on page 50. Tho total amount of the sanitary allotment for the 21 districts for the year 1896–97 was considerably under seven lakhs of rupees, showing again that want of funds, rather than want of wish to make improvements, retards progress.

10. Briefly told, the year was an unfortunate one for those who depend on the land for their livelihood, and these constitute the vast majority of the population of upwards of 35 millions. The rainfall was scanty as well as irregular in its distribution, and followed by extensive failure of crops, more especially in the Deccan districts and in the Northern Circars. This failure pressed hard on the people ; but if failure of crops and scarcity followed deficient rainfall and drought, so also did decrease of diseases due to malaria follow the same causes. Cholera prevailed in every district of the Presidency at some period during the year. Its history in 1896 cannot be said to have added much to our knowledge of its causation. The mortality from fever in Madras varies but little from year to year. Although small-pox was wide-spread, the number of deaths due to it was not excessive. Of new sanitary works, the most important were those in connection with water-supply. No definite conclusion can yet be come to regarding the influence which the execution of these works has exercised on the public health. In the first place, the water-supplies provided are not exclusively used by the inhabitants, many of the old wells and tanks being still resorted to ; and in the second place the registration of vital statistics is still so defective as to form an unsafe basis on which to rest deductions. The report is shorter than usual, but seems to omit nothing which it should include.

12th October, 1898.

No. 11.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bombay for 1896.

In accordance with the orders of the Bombay Government, vital statistics of Europeans and Eurasians are given in this report separately from those of the Native population. The former classes in point of numbers constitute an altogether insignificant portion of the population of the Presidency. According to the census of 1891 the European civil population in the Bombay Presidency, exclusive of cantonments in quasi-foreign territory, numbers only 18,486 persons, and Eurasians only 8,519. From an examination of the statement showing their distribution, it appears that the bulk of them are concentrated in the towns of Bombay, Karachi, and Poona. The birth-rate amongst Europeans is stated to have been for the year only 15·95, and the death-rate 16·44 per thousand of population. But it would be necessary to know the relative proportion which the sexes bear to each other before assigning significance to these figures. The explanation of the low ratio of births probably lies in the disproportionately large number of males as compared with females. The low death-rate follows, partly at least, from the low birth-rate ; a high death-rate accompanying a high birth-rate, as a general rule, in all communities and in all countries. Amongst Eurasians the ratios of births and deaths—18·3 of the former and 22·89 of the latter—although still low, are considerably higher than those recorded for Europeans. But it would be unsafe to draw conclusions from the recorded vital statistics of a community numbering only a few thousands. One noticeable feature of the statistics given of both Europeans and Eurasians, is the predominance of the births of male as compared with births of female children. Amongst Europeans there were 161

male to 133 female children born; and amongst Eurasians 99 male to 57 female children. Of Europeans, 188 males to 115 females died. These numbers seem to confirm the estimate made of the probable constitution of the European population in the Presidency. Of Eurasians 195 died; and of these, 111 were males and 84 were females. To be of use for purposes of comparison with the statistics of the native population, the population numbers of Europeans and Eurasians would need to be greater than they are, and the exact constitution of the communities as regards sexes and persons living at different ages would have to be known. Without such data no comparison that would not probably be misleading can be made. The diseases from which Europeans and Eurasians chiefly died were, as in the case of the natives, cholera, small-pox, fevers, and bowel-complaints. Amongst Europeans the ratio of deaths from cholera was less than half the ratio amongst natives, having been 0·71 per mille as compared with 1·8. The ratio of deaths from small-pox, contrary to what might have been anticipated, was somewhat higher amongst Europeans than amongst natives, having been 0·54 per mille as compared with only 0·34. The same was the case with regard to deaths from diarrhœa and dysentery, the ratios being higher in the case of Europeans than in the case of natives, in the proportion of 2·33 of the former to 1·92 of the latter. But it is in point of mortality from fever that the difference between the two races is greatest: whilst the recorded ratio of deaths per thousand of population was 21·90 amongst natives it was only 2·66 amongst Europeans.

2. The year under report is described by the Sanitary Commissioner as having been an unhealthy one. Its most marked meteorological features were irregularly distributed and unseasonable rainfall, higher maximum temperature and higher range of temperature than in 1895. For the first four months of the year there was practically no rain. The monsoon set in regularly in the month of June. During July and August the fall was in parts of the country so excessive as to be destructive of the crops; early in September the monsoon ceased, and there was practically no rain in October. A more or less complete destruction of the *kharif* crop was thus brought about. Some rain fell in November and December, but too late, except in certain districts, to materially improve prospects. With the failure of crops, prices rose enormously. Leaving out fractions, wheat, which could be bought at from 18 to 12 seers per rupee in January, cost double in December. Rice rose to about six seers per rupee; and the greater and lesser millets, as in the case of wheat, rose to about double the price ruling in January. These high prices caused much distress amongst the poorer, and especially amongst the landless, classes. Scarcity deepened into famine, and in the nine districts which suffered most, upwards of seven and a half millions of the population were affected. By the beginning of November State aid had to be given for the relief of distress and the saving of life. It would be contrary to all experience if, in a season of such exceptional meteorological characteristics followed by such calamitous results to the crops and by so great a rise in the price of food, the public health did not suffer.

3. *Vital Statistics.*—It is true that, in spite of the unhealthiness of 1896, there was "a very "sensible increase in the population of the Presidency"; but this increase was of course determined by conditions mainly affecting, not 1896 but its predecessor. The births exceeded the deaths by no fewer than 95,375, and the mean number of the preceding 10 years by 50,021. The recorded birth-rate for the year was 36·76 per thousand of population, against 35·83 in 1895 and a mean of 36·39 for the previous 10 years. The birth-rate of the City of Bombay continues to be exceptionally low. Evidence was given in last year's memorandum that this was in great part due to defective registration. In the Sind Division the birth-rate was 26·27, as compared with 36·76 for the Presidency. The difference is believed to be largely due, as in the case of Bombay City, to neglect of registration. Tho preponderance of male over female births, 136·93 of the former to 100 of the latter in the Upper Sind Frontier, may be taken as a measure of the neglect to register the births of female children rather than as evidence of an abnormal excess of male children born. The recorded birth-rate in towns was was 29·61 against a rural birth-rate of 37·76. This would seem to show that in spite of the greater intelligence assumed to characterise the dwellers in towns, the record in them of vital statistics is more negligently carried out than in the country. The Sanitary Commissioner is still of opinion "that overcrowding on unhealthy areas and living in badly ventilated rooms are the "causes" of the high percentage of still-born children in the City of Bombay. This may have some effect in raising the percentage; but, as the Secretary to the Government of Bombay observes in his review of the report, "the Sanitary Commissioner has not been able to adduce any facts to refute the "suggestion that the abnormally high percentage in Bombay City is due more to the great inaccuracy "of the live birth-rate on which the percentage of still-births is taken, than to any other cause."

4. The recorded death-rate for the year was 31·69 per mille of population, against 28·61 in 1895, and a decennial mean of 28·74. No doubt deaths are everywhere more carefully registered than births, yet even in regard to deaths the ratios recorded for the five Collectorates of the Sind Registration District, varying as they do from a maximum of 24·89 in Karachi Collectorate to as low as 17·46 in Hyderabad, witness to very defective registration. Bombay City, however, cannot share in this criticism. If its birth-rate of 19·35 is incredibly low, such is not the case with its death-rate of 40·99. It is curious that towns like Bombay and Nasik, which record almost the lowest birth-rates, record death-rates much above the provincial average. The rate, as already stated, for Bombay City is 40·99 and for Nasik 54·90. The very circumstance of their death-rates being so high suggests that their birth-rates of 17·18 and 17·78 respectively, are understated. It is an acknowledged axiom that a high birth-rate generally, and in the absence of special conditions, implies a high death-rate, and *vice versâ*. This may be illustrated by reference to the table on page 19 of the report. The six towns which give the highest birth-rates also give death-rates above the provincial average. Omitting the first, which, with a birth-rate of 61·46 gives a death-rate of only 32·31, the other five, with birth-rates running between 48·26 and 56·26, have also death-rates varying from 38·92 to 51·19.

5. The death ratio of 179·38 for infants under one year of age in the Bombay Presidency is pretty high, but cannot be said to be excessive. The corresponding ratio for Madras was 124·7, and for the Central Provinces 318·14. In Madras, registration is admitted to be still very defective. The months of highest mortality were July and August: they were also the months

of greatest cholera prevalence. Although the last three months of the year were months of severe scarcity, their death-rates are the lowest of the twelve. This was no doubt due to the subsidence earlier in the season of cholera, and to lesser prevalence of malarial diseases consequent upon the premature cessation of the rains and the resulting unusual dryness of the last three months of the year. Besides, the Government, anticipating from the failure of the crops that privation would follow, promptly came to the relief of the distressed and preserved the lives of thousands who, but for this timely aid, would have succumbed. The recorded ratio of deaths among Hindus was 33·74 per mille; and among Mahomadans only 24·48. The comparatively low death-rate among Mahomadans "is attributed to the very defective registration in the rural areas of Sind, "where the system is in its infancy."

6. *History of Chief Diseases.*—Cholera was accountable for 35,404 deaths, or four times as many as during the preceding year. The three first and the three last months of the year were those of greatest immunity from the disease; whilst July was the month of, by far, its greatest prevalence. The Sanitary Commissioner gives a table showing the mortality from cholera by seasons. From this he finds that 23,501 deaths occurred in the rainy season of 122 days, and 8,850 in the hot and dry season of 61 days. Some of the Deputy Commissioners, in their remarks, would seem to imply their belief in some connection between rainfall and cholera prevalence. Regarding the outbreak in Khándeish we find:—"All the rural circles were "affected. It is stated to have been imported from the Hyderabad Assigned Districts. The "mean temperature was unusually high, the rainfall less, and the price of food grains was "about the average during the period of the outbreak. There was a heavy rainfall in July; "and by the end of September, the rains having ceased, the disease practically disappeared." At the commencement of the outbreak in this case, the conditions appear to have been unusually high temperature and unusually scanty rainfall; whilst the cessation of the disease was preceded by heavy rainfall with, it may be presumed, a consequent decrease of the temperature. In the Bijapur District cholera was excessively prevalent, causing 5,249 deaths. Dr. Clarkson "is of "opinion that the large number of step-wells is one of the causes of the recurrence year after "year in that district." In some circles of the Ahmednaggar, Poona, and Bijapur Collectorates the mortality was very great, rising to a ratio, per thousand of population, of 12·68 and 14·74. The cause of the escape of one village or town and the invasion of its neighbour, both being apparently alike as regards their sanitary condition, seems to be as far from discovery as ever. Out of 21,608 villages in the districts affected by cholera, 2,642, or 12·23 per cent., were attacked during the year.

7. *Small-pox* caused 6,443 deaths, or nearly three times as many as during the preceding year, and more than double the decennial mean. Of the total number of deaths, 1,901 occurred amongst infants under one year of age, and 3,336 amongst children over one year and under 12 years; so that only 1,206 remain to be accounted for amongst persons of upwards of 12 years of age. But although the death-rate was higher than usual, it only amounted to a ratio of 0·34 per mille of population. Notwithstanding that vaccination work must have been impeded owing to the prevalence of plague, and to the floods in Sind, the numbers vaccinated show no sensible decrease for the year. There was a slight increase in the number of primary vaccinations, and a slight decrease in the number of re-vaccinations, the total of both being only 81 below the total for the previous year. The percentage of success was practically the same in both years. In the City of Bombay animal lymph was exclusively used in vaccination. A question was raised regarding the likelihood of the transmission of plague by means of vaccine lymph. The Sanitary Commissioner thinks that, as regards calf-to-arm vaccination, at all events, there is no danger; and, as a matter of fact, there was no report of the communication of plague by animal vaccination. It was nevertheless considered prudent to put a stop to arm-to-arm vaccination in plague centres, although there was no evidence that plague could be propagated in this way.

8. *Fevers*, as usual, were the chief cause of mortality during the past as during every year. The deaths recorded as due to them numbered 412,229, being an increase of 23,381 over the number in 1895. It was no more than was to be looked for that, following the scanty rainfall and early cessation of the monsoon, the last three months of the year should enjoy comparative immunity from fever; but it was contrary to expectation that, in face of lessened fever prevalence during these three months when fever is usually most fatal, the total fever mortality of the year should be above the normal. The returns show that deaths from fever were more numerous during October, November, and December of each of the years 1892–93 and 1894 than in the same months of the subsequent years 1895 and 1896. That this greater fatality was due to the more than average rainfall in the three former years, and that the lesser fatality in the two latter years was due to their scanty rainfall, may be accepted as extremely probable. But the cause of increased mortality from fever during the other nine months of 1896 is not so easily accounted for. One explanation offered is that a large number of deaths from other causes during these months was wrongly attributed to fever. But seeing that the same defective diagnosis and record of disease are in operation every year, the explanation does not seem to be quite adequate. A similar high rate of mortality prevailed during the first half of the year in Berar, and was believed to be due to influenza; but of the existence of this disease in the adjoining parts of the Province of Bombay there is no mention, although it is reasonable to suppose that, if influenza was so widely prevalent in Berar as to be sufficient to account for the high death-rate wrongly attributed to fever in the first months of 1896, it may also have prevailed in the districts of Bombay continuous with those of Berar.

9. *Plague* was first diagnosed in Bombay City by Dr. Viegas on the 18th of September. Whether it existed in the town earlier, or whether it was imported, and by what agency, are questions to which answers are not easily given. Its rate of progress at first was not rapid, and 2,908 cases, with 2,086 deaths, were reported up to the end of the year. There may be doubts as to the way by which the disease found entrance into Bombay; but there are none as to how it spread from there into other parts of the country. The first cases of plague which

were detected in Ahmedabad, Poona, and other towns were without exception imported cases. The Sanitary Commissioner is in favour of drastic measures for dealing with plague. "All persons, not "sick but coming, or suspected to come, from an infected area should be put under observation for "10 days. The persons and clothes disinfected both on arrival and departure from camp." In the light of the further history of the progress of plague in India, the Sanitary Commissioner might be disposed to modify his recommendations. The very measures adopted to stamp out the disease have been found, as similar measures have been found in India, to defeat their purpose and aid its propagation. The removal of cholera-stricken persons from their houses to cholera hospitals at once leads to concealment of the disease: similar removal of persons plague-stricken or "suspected" of being so has led to a like result, and in some cases to violent resistance ending in loss of life. Worst of all, it has failed to stop the progress of the disease. "Air, light, and cleanliness appear to have a "great effect on the disease," so writes Dr. Clarkson; and if the inhabitants of affected towns and villages could be induced to submit themselves and their towns and villages to the action of these ordinary agents, more drastic remedies would not generally be required. But the evacuation of large towns and cities for a time by their inhabitants stands on a different level from the evacuation of a plague-stricken village in the Himalayahs. Were it practicable, however, there is little reason to doubt that it would prove as effectual in putting an end to plague in the one case as in the other.

10. Twenty pages of printed matter are devoted to an account of the proceedings of the Sanitary Board. The report is largely taken up with technical details of sanitary works. Probably few readers, other than engineers, would make much of the following quotation taken from page 2 of the Board's report:—"(*e.*) The R.L. of the low-water level of reservoir, and of F.S.L. of No. 1 Cistern, "give a minimum 'head' available of 3·5 feet. The size of pipe to give 42 gallons a minute will be "6 inches in diameter." The omission of the greater part of the details given in the report would not much, if at all, impair its usefulness, and would meet a general desire, which is well expressed in the concluding sentence of the review of the report of the Sanitary Commissioner of the Hyderabad Assigned Districts. "The increasing voluminousness of annual reports has become a serious evil, "and the head of a department who can compress into the fewest and shortest paragraphs an "adequate account of the year's work will deserve, and will certainly obtain, the Resident's "profoundest gratitude."

11. On *Sanitary works*, in the 167 municipalities, excluding Bombay City, out of an income of about fifty-five and a quarter lakhs of rupees, a sum of over twenty-two and a quarter lakhs was expended during the year. Of this latter amount, nearly six and a half lakhs went towards the improvement of water-supply. The account given of the progress being made with the provision of water-supplies for municipalities does not afford much ground for hope that many of the projected works will be undertaken in the near future. Taking the description given of the stage which the water-supply schemes have reached in a few of the municipalities:—*Barsi*, "the water-supply "project for this place has been shelved by the municipality on the strength of an unfavourable "analysis of one well." In *Pandhrapur*, "the much-needed improvements to the water-supply in "the interests of the numerous pilgrims has not proceeded beyond discussion for several years." In *Wai*, "proposals for water-supply and drainage, as in the case of Nasik, have been under discussion "for many years, but have progressed no further." The income of the District Local Boards for the same year amounted to just over forty lakhs of rupees, but less than seven lakhs of this sum was allotted for sanitary purposes. The greater part of the allotment was devoted to the improvement of water-supply. Needless to say, such sums can go but a very short way in carrying out permanent works of sanitary improvement. Want of funds in the Bombay Presidency, as everywhere else, is the main obstacle in the way of sanitary progress.

12. Briefly told, the year 1896 was an unhealthy one. It was characterised by a high maximum temperature, and by a scanty and irregular rainfall. The birth-rate was higher than it was during the preceding year, to the comparative healthiness of which this increase was doubtless due. The death-rate also exceeded that of 1895. High prices and consequent distress prevailed towards the end of the year. Cholera was four times more fatal than in 1895, and small-pox nearly three times. Fever, although less fatal during the months when it is ordinarily most fatal—the last months of the year—has a greater number of deaths recorded against it than during the preceding year. Plague was first recognised in Bombay City on the 18th of September, and slowly increased during the remaining period of the year. From Bombay it was carried into towns in the interior. By the end of the year, 2,908 attacks and 2,086 deaths had been recorded as due to it. Sanitary improvements in municipalities and in rural areas were retarded owing chiefly to a want of a sufficiency of funds. A report of the Sanitary Board covering 20 pages and concerned mainly with technical descriptions of water-works, drainage, &c., might, perhaps, in future be abridged. This would have the effect of reducing the bulk of the Sanitary Commissioner's Report without appreciably lessening its value.

12th October, 1898.

No. 12.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Hyderabad Assigned Districts for 1896.

If the year 1895 was characterised by a light rainfall and an abnormally high maximum temperature, its successor, 1896, presented the same characteristics in a more marked degree. In the former year the rainfall measured 27·3 inches, and in the year under notice only 26·6 inches; whilst the maximum temperature of 1896 was 93·1 as compared with 91·0 in 1895. The mean

maximum temperature was 90·5 and the mean rainfall 40·8 inches during the previous five years. The effects of this short rainfall and high temperature on the crops and on the public health of the province were what might have been anticipated. Partial failure of the autumn, and almost complete failure of the winter, crops followed deficient rainfall; whilst diminution of the malarial diseases, which annually prevail during or after the monsoon, is considered to have been due to the dryness consequent on this lessened fall of rain.

2. *Vital Statistics.*—Attention continues to be given to the inspection of registration of births and deaths. Judging, however, from the recorded results of the inspections made by officers other than those of the Vaccination Department, these inspections, as the Sanitary Commissioner remarks, "often appear to be performed in a very cursory or perfunctory manner." If such really be the case they had probably better not be performed at all; careless testing of them can only tend to breed carelessness in those who keep the registers, by lessening the fear of their shortcomings being found out. A comparison of the entries in the registers with the results of a house-to-house inquiry is the only form of inspection worthy of the name. This method has been followed by the Superintendents of Vaccination, who, during the year have examined 2,872 village registers. Of this number, 240 were found to contain errors of omission, the total of the omissions having been 371 births and 152 deaths. This margin of error, although considerable, is probably still below the reality. Although in municipal towns "it is obligatory for the head of "a family in which a birth or death takes place to report this occurrence," it is found that in most municipalities registration is more defective than in villages—a result which the Sanitary Commissioner believes to be due to a want of interest on the part of municipal authorities. "There is, however," the Commissioner thinks, "some improvement, and 90 persons were "prosecuted during the year for neglect to register, and fines aggregating Rs. 71 were imposed."

3. The *births* were more numerous by 3,061 than during the preceding year; and their ratio per thousand of population increased from 37·2 in 1895 to 38·3 in the year under report. This rate is considerably below the mean of 40·7 for the 10 years ending 1890, and still further below the actuarial estimate for India of 48·8. The preceding two years were distinctly unhealthy, and cannot have failed to exercise an adverse influence on fecundity during 1896. In spite of the persistent efforts to improve registration there is still, as shown by the results obtained by testing the registers, a considerable percentage of births which escape registration.

4. The number of *deaths* fell below the number recorded for 1895 by 17,150; and the ratio per thousand of population from 49·9 to 43·8. In the neighbouring Central Provinces, by which Berar is to a considerable extent surrounded, the reverse was the case, the death-rate rose from 36·75 in 1895 to 49·31 in 1896. Yet, although the death-rate in Berar decreased by 6·1 per thousand of population, it was still largely above the average of 38·8 for the preceding five years. The recorded number of deaths also exceeded the recorded number of births by 13,774. Indeed, for the past three years the deaths have largely exceeded the recorded number of births, and there must be an appreciable reduction of population going on, unless the loss resulting from excess of deaths over births is being made good by immigration, and of this there is no mention. A remarkable feature of the year is the inversion of the seasons of greatest mortality. Instead of low death-rates being recorded during the first five months of 1896, we find the number of deaths rising from 10,573 in January to 13,263 in March, and reaching a maximum of 16,119 in April; whilst in August it has again fallen to 11,796, in September to 10,839; and in October and November to 9,104 and 6,832 respectively. "The healthiest months were June, December, and November, and the most unhealthy "April, May, and March; thus, contrary to previous experience, the first half of the year was the "most sickly, and of the four quarters the fewest deaths were registered in the fourth." The explanation of this anomaly does not appear to be entirely satisfactory. The Sanitary Commissioner writes:—"This deviation from the ordinary in the seasonal incidence of mortality is, I believe, "to be explained by the abnormally hot weather which prevailed during the first half of the year, "operating as a disturbing factor in lowering the public health, and by the exceptionally low "rain-fall in the third quarter, reducing to a minimum those monsoon conditions which tend to "raise the death-rate." With the latter part of this explanation it is possible to agree; exceptionally low rain-fall in the third quarter, or in other words an unusually dry autumn, is consistent with a diminished prevalence of malaria and of the diseases which are attributed to it. But something more than abnormal heat lowering the public health during the first half of the year is required to explain the high mortality in March and April. If this was the cause, we would have expected the mortality to have increased in May and June; whereas the number of deaths fell rapidly from 16,119 in April to 13,375 in May, and to 6,196 in June. If the prevalence of cholera had any connection with the unusual heat in the early months of the year, this might to some extent account for the great number of deaths in March, April, and May. As a matter of fact, to whatever cause due, cholera accounted for 1,055, 2,869, and 2,310 deaths in each of those months respectively. But, although cholera has been shown to have contributed to this high death-rate in the early months of the year, the principal cause was fever. This disease is credited with over 7,000 deaths in each of the months of March and April and over 6,000 in May, as compared with over 4,000 deaths only in each of the ordinary fever months of August, September, and October. Evidently, the Sanitary Commissioner is not himself satisfied with the explanation which has been quoted from his report, for in paragraph 33 he writes:—"This unusual fever mortality during the first "five months of the year is, I believe, attributable to epidemic influenza."

5. *Chief Diseases.*—In every month and in every district cholera was prevalent during the year. The same was the case in the preceding year. An examination of Table 19, page 17, will show that in 1895 and 1896 the general course of the disease was not very dissimilar in both years; and that the number of deaths in each was nearly the same. In the former year it caused 11,919 and in the latter 12,264 deaths. The ratio of deaths per thousand of population was also, of course, nearly the same—4·2 in 1895 and 4·3 in 1896. After these two years of severe cholera epidemics the Sanitary Commissioner ventures on a prediction. "From the experience

" of previous years," he says, " we may expect that 1897 will be one of comparative quiescence of the " disease." In the present state of our knowledge, or ignorance, of the ways of cholera, it is somewhat unsafe to prophesy regarding its future. " After the storm generally comes a calm," writes Dr. Little; but in this instance the subsidence of the mortality in the last months of 1896 will be found to have been delusive, and not to have preceded a calm. A striking feature in the cholera history of the year, it is said, is its seasonal distribution as compared with former years. An examination of the return from which this deduction is drawn does not seem to disclose any very striking feature in the course of the epidemic of 1896 as compared with that of 1895, or with the ordinary course which cholera in Berar generally follows. In 1896 the first two and the last three months of the year are the months of lowest cholera mortality: the same is the case as regards 1895; whilst the mean of the previous 10 years only deviates from this in that the first three and the last two months are those of least cholera mortality. The main difference between the progress of cholera in 1896 and in other years seems to be chiefly in its having increased more rapidly than ordinarily towards its climax in April and May, in this respect bearing some resemblance to its course in 1889. Although the months of August and September were not, as usual, the months of its greatest prevalence, they were still months of great prevalence, the death-rate in each falling little short of the mean for those months. Looking at the table already referred to, the one feature visible in all years is the comparative immunity from cholera mortality of the earlier and of the latter months of each. It may be a question for consideration whether the abnormally high temperature which characterised the years 1895 and 1896 may not have had some influence upon the course of the disease in both years. Certain it is that both years were marked by abnormally high temperatures, and that both were years of severe cholera prevalence.

6. "The reports of first outbreaks from Civil Surgeons do not represent any novel features as " tending to elucidate the mode of origin and spread of the disease;" but evidence is given to demonstrate the acknowledged connection between water-supply and cholera. One sample of such evidence will suffice. Surgeon-Major Roe, Civil Surgeon of Amraoti, after describing how the water-supply of the town of Amraoti gave out early in the year, and stating that cholera began on the 9th of January and ended 10 months later—245 persons having been attacked during this period—goes on to say :—" One interesting point was brought out here. On the 12th February there were 22 attacks, " about 18 of which were among Mahomadans; on the 13th there were 18 attacks, some 14 being " Mahomadans. I then found that the disease was being carried by *bhisties* who supplied water " from dirty *jhiras*, situated in the Amba *nullah*. A guard was placed over the *nullahs*, and " the cholera ceased." We are told nothing about the proportion which Mahomadans bear to the rest of the population: even the number of Mahomadans attacked is vaguely stated to be "about" 18 or "some" 14. It would have been interesting to have been told how Dr. Roe "found that the " disease was being carried by *bhisties*," and also to have had the date given when the guard was placed over the nullahs, and the date on which, following this, cholera ceased. The Sanitary Commissioner observes that the practical failure of the water-supplies was sufficient of itself to raise the death-rate generally, and thinks it very probable that a return to unused wells and river water rendered the people more liable to cholera. There can be little question that the unusual prevalence of cholera was connected with the excessive heat and drought, which rendered the water-supplies of the province scanty and impure.

7. *Small-pox.*—The total number of deaths registered from this disease was 810 as compared with 556 during the previous year. The ratio of deaths per thousand of population was 0·3 as compared with 0·1 the quinquennial mean, and 0·3 the mean of the 10 years ending 1890. The disease cannot, therefore, be said to have been very prevalent or fatal during the year. The single district of Amraoti returns 415 small-pox deaths, or more than half of the total number for the province. But it was discovered that deaths from influenza were being registered under the name of *kapsi matha*, or " cotton-pox," as small-pox; and although the mistake was remedied as far as possible, the Sanitary Commissioner believes that the error led to the recorded number of small-pox deaths being raised somewhat beyond the real number in the Amraoti district. Vaccination made satisfactory progress during the year. The number of operations increased by 12·6 per cent. as compared with the number for the preceding year; whilst the percentage of successful cases in primary vaccination rose from 95·9 to 96·8. On the other hand, the percentage of success in re-vaccination was only 20·5. The contrast between this percentage in re-vaccination and that recorded in some other provinces is remarkable. In Madras, for example, 80·2 of the re-vaccination operations are stated to have been successful. Of every 100 persons vaccinated in Berar 81·1 were infants, and 16·3 children between one and six; whilst only 2·5 were of other ages. Deducting the number of deaths of infants registered during the vaccination year 1896-97 from the total number of children born, there remained 85,879 available for vaccination, and of this number 77,490, or 90·2 per cent., were protected against small-pox by vaccination, leaving an unprotected residuum of 8,389. Dr. Little has found it possible to dispense entirely with arm-to-arm vaccination: calf lymph only is used in Berar. His own experience, he says, is in favour of direct vaccination from the calf; but he thinks the time may come when it will be necessary to carry on vaccination entirely with lanoline paste lymph.

8. *Fevers* are credited with having caused 61,930 deaths as compared with 66,203 in the previous year, and with a mean of 42,124 in the decennial period ending 1890. Ordinarily, fevers are most prevalent and fatal in the months succeeding the setting in of the monsoon, especially in the months of August and September; but during the past year they attained their maximum prevalence in March and April, and their minimum in June and December. The inquiries of the Sanitary Commissioner, as already stated, have led him to attribute this abnormal prevalence of fever in the early months of the year to the epidemic of influenza, which hospital assistants, as a rule, failed to diagnose. The latter disease, as seen by Dr. Little in the villages, was characterised by "sudden " invasion, high temperature, pains in back, limbs, and head, no catarrhal symptoms, great " prostration, and pneumonia as a sequel proving fatal.".

9. *Bubonic Plague.*—Two fatal cases of this disease were reported during the month of October. Both of the persons attacked are believed to have become infected in Bombay, where the disease was prevalent and from which both had just come. Only one of the cases would appear to have been seen by a medical officer. According to the description given by the hospital assistant who saw this case, there can be little doubt that it was one of genuine plague. The body of the deceased was cremated, and the house first occupied by him, as well as that in which he subsequently died were fumigated with sulphur and afterwards lime-washed. There was no other case of the disease in the Buldana district in which this man died. The other man did not apply for treatment; he died on the 11th of October, after suffering from fever and glandular swellings in his groin, since his arrival on the 4th of the same month. He was accompanied from Bombay by two men, three women, and two children. One of the men returned to Bombay; the other six persons are reported to be still residing at Akot, where the man died, and to have escaped infection.

10. *Dysentery and Diarrhœa.*—These diseases were less fatal than during the preceding year, the ratio of deaths due to them falling from 8·6 in 1895 to 6·2 in 1896. Still, the ratio was above the mean of the 10 years ending 1890. Ordinarily, bowel-complaints, like malarial fever, prevail with the greatest severity in the autumn months; but during 1896 their incidence corresponded with that of fever and influenza. It has already been noted that these last were most fatal during the first six months of 1896. The prevalence of bowel-complaints kept time with that of fevers, dysentery and diarrhœa having been unusually fatal during the first five months of the year.

11. *Sanitary Works.*—In Berar, as elsewhere, the want of funds is the main obstacle in the way of a more active prosecution of sanitary improvements. The money available is being chiefly devoted to the provision of a pure water-supply for the towns of the province. Out of a total estimated income of a little less than two and a half lakhs of rupees, the municipalities expended on water-supply Rs. 71,180, besides Rs. 59,988 on domestic cleansing, and Rs. 29,139 on other sanitary works, making a total under these three heads of about 70 per cent. of their estimated income for the year. Sanitary Boards are reminded by the Resident in his resolution attached to the report of the sound "principle that permanent improvements are to be preferred to temporary cleansings." Such advice is timely when it is seen that out of a total expenditure of Rs. 82,695 on sanitary works during the year, no less than Rs. 37,215 were expended on domestic cleansing, whilst only Rs. 28,950 were expended on water-supply, and Rs. 12,690 on drainage.

12. A table is given showing the progress made in his sanitary surveys by the Sanitary Commissioner from the year 1888 to 1896. During the year under report, one town and 152 villages were surveyed, making a total to the end of 1896 of 36 towns and 804 villages. Three more towns and 4,439 villages in the province remain to be surveyed. At the rate of 100 each year, it will take 44 more years to complete the survey of the remaining villages. The proposal of the Government of India to prepare and maintain a permanent sanitary record for villages has been adopted in Berar, and the Resident has directed that the record should be kept in five villages in each district, or in a total of 30 for the province.

13. In the concluding paragraph of our last year's memorandum on the report of the Sanitary Commissioner of the Hyderabad Assigned Districts, when it was proposed that "legislation" should be brought to the aid of sanitary reform, we suggested that education would be preferable to legislation. During the year under review, proposals to legalise a system of village sanitation were, under orders from the Resident, circulated throughout the province for the purpose of eliciting native opinion on the subject. One and all of those consulted "were opposed to any legislative "interference with the customs of the people in connection with sanitary reform. Some of the "more moderate and intelligent native gentlemen are strongly of opinion that the time for "legislation has not yet come, and that to press any measure of sanitary reform in opposition to "the sentiments of the people would give great and universal dissatisfaction." The Sanitary Commissioner adds:—"In deference, therefore, to native opinion, I have withdrawn my proposals "to enforce village sanitation by legislation."

14. Briefly described, the year was one of deficient and unseasonable rainfall, followed by partial failure of the autumn, and almost complete failure of the winter, crops. The unusually high temperature of the year and deficient water-supply are believed to have exercised an injurious influence on the public health. Fever, influenza, and cholera combined to raise the death-rate to an abnormal height during the first half of the year. On the other hand, deficient rainfall seems to have lessened the prevalence of malarial diseases during the last half of the year. What of funds were available were chiefly employed by municipalities in improving their water-supplies. The proposal to enforce sanitary reform in villages by legislation has been, for the present, abandoned in deference to native opinion. The Resident, whilst thanking the Sanitary Commissioner for his report, "begs that in future, earnest endeavours may be made to largely curtail it, and to exclude, as "far as possible, all tabular statements other than those prescribed by authority.

12th October 1898.

No. 13.

Memorandum by the Army Sanitary Commissioner on the Administrative Report of the Town of Calcutta for 1896–97.

Judged by its record of vital statistics, the year 1896 was healthier than its predecessor. There was a substantial increase in the birth-rate, and a still more substantial decrease in the death-rate. In the paragraph sketching the chief meteorological features of the year no mention is made of deviations from normal, nor of the favourable or unfavourable influence exercised by the weather on the public health. The price of food was higher than the average of the preceding ten years.

2. The number of live *births* exceeded the number for either of the two preceding years, but was below the number for 1893. As in the case of Bombay City, the birth-rate in Calcutta is only about half the death-rate. During the year under report, the recorded ratio of births was 18·4, and of deaths 35·7, as compared with 16·0 of the former and 39·6 of the latter in 18.5. An examination of the statement of births on page 290, Part II. of the Report, shows the influence of the disproportion of the sexes in the population on the birth-rate. Where, as in Waterloo Street, there is a population of 6,083, of whom only 500 are females, the recorded birth-rate is 4·4 per mille. In Burra Bazar, with a population of 20,646, of whom the females number only 4,120, the recorded birth-rate is 5·9. In Colootollah, with a population of 50,781, of whom the females number only 15,466, the recorded birth-rate is 9·7. At the same time, this disparity in the number of the sexes is not accompanied by such abnormally low birth-rates in all of the registration circles. For example, in Hastings circle, out of a population of 4,820, only 1,582 are females, yet a birth-rate of 32·1 is recorded: in Collinga, out of a population of 13,218 there are only 4,321 females, and yet the birth-rate is recorded to have been 24·9. It thus appears that, although the preponderance of males in the population has a marked effect, as must always necessarily be the case, in lowering the birth-rate, there may be other influences concerned in bringing about this result.

3. The *death-rate* fell from 39·6 in 1895 to 35·7 in the year under report, but was still almost double the birth-rate. Compared also with the average rate of the five years preceding the unusually unhealthy year 1895, the death-rate of the year under report was still very high. As usual, the death-rate of the Canal area was the highest. This could scarcely be otherwise if the description given of it in the Health Officer's report of last year still holds good. It was then described as low-lying, water-logged, and sewage-logged to a greater extent than any other part of the town. "The decline in the public health," writes Dr. Simpson, "in comparison to the previous five years, "was greater in the town area than in the suburban area, and in the area bordering on the Circular "Canal than in the rest of the suburbs." The tendency of the death-rate of the drained town area to overtake the high death-rate of the undrained suburban area, Dr. Simpson in previous reports attributes to the defects in the drainage system of the former, placing it in the rainy season in much the same position as the undrained suburban area, and to the consequent increase of fever mortality. Infant mortality continues to be lamentably high. Taking the town and suburban mortality combined, the death-rate amongst children under one year of age was 435·4. In the town of Calcutta, taken by itself, almost half of the children born, or 494·7 of every 1,000, died before reaching their first year. Of the male children by themselves, 503·7, or more than half the number born, died within their first year.

4. *Cholera* mortality was largely in excess of that of the previous year. There were 3,449 deaths from this cause, a number not exceeded from the time the records of mortality from cholera in the old town and suburbs were combined in 1889. Such a result, after many years of persistent endeavour to improve the sanitary condition of Calcutta, and the expenditure of vast sums of money in providing it with a pure water-supply, must be somewhat disappointing. But no one who has read the description given by the Health Officer of the sanitary state of the town, even at the present day, will be surprised at the destructive effects of the epidemics of cholera by which it still continues to be visited. Water is doubtless one of the chief means by which the disease is diffused, but it is probably not the only one, and it would be unwise to devote exclusive attention to this one avenue of ingress of the disease to the neglect of others which may seem less important. It would have been interesting to have had some explanation of the reasons why "the added area of Shampooker" had a death-rate from cholera of 8·7 per thousand of its population, and "Collinga Ward" only 1·3. Dr. Simpson endeavours to trace a connection between the use of unfiltered water at the bathing platforms and cholera. He states that a bacteriological examination "showed that *comma bacilli* "were in the river and bathing-platform waters, and that the highest percentage of instances in which "*comma bacilli* were present in the water was practically synchronous with the greatest prevalence "of cholera in the town." It is presumed from this account that those bathing must have drank of the unfiltered water in which they were bathing. Even so, it remains to be proved that the drinking of the water containing the *comma bacillus* caused cholera. So far, the causal relation between the *comma bacillus* and cholera is by no means the established fact which some assume it to be. The Municipal Commissioners resolved to continue the anticholeraic inoculation experiment until the end of the financial year, when operations conducted on their own account ceased. From this decision the inference may perhaps be drawn that anticholeraic inoculation has not achieved the success at first expected by some of its more sanguine advocates.

5. *Small-pox* appears to have expended its virulence during the preceding year, when it carried off no fewer than 2,220 persons. Only 69 deaths were attributed to it in 1896. Until the outbreak of 1895, in no year since 1878 did the number of deaths from small-pox reach a thousand. For the next five or six years, whilst the number of persons unprotected by vaccination is re-accumulating, the disease will probably remain more or less quiescent—again breaking out in epidemic form of a

severity proportioned to the number of persons who have not been vaccinated or re-vaccinated. There was a great falling-off in the numbers vaccinated during the year under report as compared with the numbers in the previous year. The prevalence of small-pox in 1895 had the effect of giving to both primary vaccination and re-vaccination a strong stimulus. The total number vaccinated during the year under report was only 11,976 against 54,982 in the previous year. The percentage of success in ascertained cases of primary vaccination was 95·4, and in re-vaccination 14·3. These latter figures contrast in a remarkable manner with those for Madras City. In Madras the percentage of successful cases in re-vaccination is recorded to have been 87·11. Of children who were vaccinated whilst under one year of age there were 2,936; whilst the number of children born alive was 12,608. Even if half of these latter died in their first year, and the actual number was somewhat less, there would remain available for vaccination 6,304. Of these, it is stated that 2,936 were vaccinated; but from this number should be deducted the unsuccessful cases, the doubtful and the unknown. In Statement III., Vaccination, page 330, Part II. of the Report, the number of cases according to age seems to include all operations, successful or otherwise. It would be a great convenience for purposes of comparison if the Calcutta Municipality would furnish Statement No. 1., showing particulars of vaccination. This is the Statement authorized by the Government of India, and is furnished with the Annual Report of every Province and Presidency town except Calcutta.

6. Although there was a decrease in the ratio of mortality from *fevers* from 16·6 per mille of population to 14·0, yet the ratio was in excess of the average of the five-year period 1891-95 when it was 12·9. The Health Officer gives a table to show that a gradual but steady increase in the death-rate from fevers has been going on in the old town since 1889.

7. When the report of the outbreak of *bubonic plague* in Bombay was confirmed, measures were taken by the Municipal authorities of Calcutta with the object of endeavouring to prevent importation of the disease as well as of stamping it out, should it unfortunately effect an entry into their city. It was discovered that a young man who had come to Howrah from Bombay on the 26th September was suffering from a complaint which the Health Officer and two other medical men pronounced to be *pestis ambulans*; but the "Medical Board, investigating the case later on, came to the conclusion that "there was no evidence to consider this a case of true bubonic plague." The fact that no case of plague appeared in Calcutta for the rest of the year would seem to confirm the accuracy of the Board's finding. The wisdom of some of the proposals made by the Health Officer with the view of protecting Calcutta from an invasion of plague, seems open to question, especially when looked at in the light of subsequent events. He says:—"I went so far as to propose that all passengers, except "first-class passengers whose destination can easily be traced, should undergo detention for seven "days before being allowed to enter Bengal." The reasons assigned for the advocacy of this quarantine measure "are that the conditions, medical, sanitary, and social, are quite different here "from what they are in Europe." The proposals assume that all passengers enter Bengal by railway, and that quarantine can be effectually carried out in India. The first assumption is, of course, untenable, and the second has been found by experience to be impracticable when attempted in the case of other diseases such as cholera. Perhaps in no other country would it be more difficult to enforce effectual quarantine than in India, or in no other country would quarantine rules be so easily evaded.

8. *Sanitary Works.*—One useful result will have followed the fear of an invasion of plague. Calcutta has been brought to recognise the need for expedition in carrying into effect measures of sanitary improvement which, in the absence of the imminence of the danger of such invasion, might have been allowed to stand over until the proverbial more convenient season. "The year, if it were "memorable for nothing else, would be most noteworthy in the history of the town because it has "witnessed the inception and commencement of sanitary works of the highest importance." The first of these is the extension of the unfiltered water-supply. The present supply is said to be insufficient even for street-watering; whilst proper flushing of the sewers is out of the question. "The work now undertaken by the Corporation will, it is hoped, not only greatly improve the state "and efficiency of the existing sewers, but will also render possible connections of private privies "with the sewers, and thus in time largely diminish the night-soil establishment." As regards another of the great sanitary works undertaken during the year, it is said:—"Of equal, or even "greater importance are the works which have been commenced, with a view to improve the outfall "of the sewers of the town proper, to provide for the drainage of the suburbs and of the area between "the Canal and the Circular Road." The foundation-stone of the drainage works was laid by the Lieutenant-Governor on the 26th November 1896. Hardly behind these two great works in importance is the appointment of the Building Commission. The Health Officer thinks this appointment will be "the commencement of a new era in the sanitation of Calcutta, for it is the first serious attempt to "inquire into and deal practically with the ever-increasing irregular growth of the town and the "suburbs, and with overcrowded and unhealthy areas. It is this irregular growth which interferes "with every sanitary reform, and it has reached even for Calcutta to such an extraordinary stage in "Burra Bazar and Jora Bagan, as to render these districts as bad, if not worse, than any to be found "in any eastern city. The condition of the worst of these areas is indescribable." Besides accelerating the inception and prosecution of improvements calculated to exercise a radically salutary influence on the future sanitary condition of Calcutta, the plague scare has given a healthy stimulus to the every-day cleansing of the town.

9. Briefly, the year was healthier than its predecessor: its birth-rate was higher and its death-rate lower. A severe epidemic of cholera carried off 3,449 persons, a number not exceeded since the records of mortality for the old town and suburbs were combined in 1889. The Health Officer connects the outbreak with the presence of the *comma bacillus* in the unfiltered water used at the bathing platforms. Having used up during the previous year the susceptible material available, small-pox was in comparative abeyance and was credited with only 69 deaths. It would be a great convenience in comparing the statistics of vaccination in Calcutta with those in other towns, if the authorized form of Statement No. I., showing particulars of vaccination, were annually submitted by

the Health Officer with his report. There was a considerable decrease in fever mortality in 1896 as compared with its predecessor. The outbreak of bubonic plague in Bombay aroused fears of its importation into Calcutta and active steps were taken to meet the danger. The imminence of the danger of a plague invasion seems to have given a healthy stimulus to the inception and prosecution of much-needed and important sanitary works. The appointment of a Commission to regulate the erection of buildings is regarded by the Health Officer as the commencement of a new era in the sanitary history of the town, and as giving a final check to the perpetuation of the rookeries and slums which are such marked features of Calcutta.

12th October 1898.

No. 14.

Memorandum by the Army Sanitary Commission on the Administration Report of the Madras Municipality for 1896-97.

From a health point of view the history of Madras for the year was uneventful. Although meteorological conditions were abnormal, and the prices of food rose to a great height, especially during the last months of 1896, their influence had no appreciable effect in raising the death-rate, which was practically the same as during the previous year and somewhat below the average for the 10 years 1887-96. The year under report was characterised by excessive temperature and deficient wind, accompanied by short rainfall during the first seven months and excess of rain in the last two months. The rainfall between the middle of October and the end of the year measured 52·9 inches against an average for the same period of 27·6 inches. The price of rice, which was 11 seers for a rupee in January, had risen by the end of the year to eight seers and nine chittacks; whilst the price of *ragi*, a staple food grain of the poor, rose in the same period from 22 seers and three chittacks to 15 seers and eight chittacks. "The prolonged dearness of the staple food grains "cannot but exercise a potent influence on the mortality of the poorer classes, seeing that it is not "counterbalanced by a proportionate rise in the wage of labour." It is pointed out that ever since the setting-in of the series of lean years beginning with 1889 the death-rate has been high. In 1888 the rate was just over 34, and since then has only once fallen below 37 per mille of population.

2. The *births* during 1896 numbered 18,684, exclusive of still-births, and, although in excess of the number for any other year in the decade, were fewer by 453 than in the preceding year. The ratio per thousand of the population of the Census of 1891 was 41·2. The contrast between the birth-rates of the cities of Madras and Bombay is remarkable. In the latter, the recorded rate is 19·33 for the same year, or considerably less than half the Madras rate. In Madras, the number of still-births registered was 504 to 18,684 live-births: in Bombay the number of still-births was 1,598 to 15,890 live births. The difference is striking, and seems incapable of explanation except on the assumption that a large proportion of the live-births in Bombay escape registration. The still-births in Bombay being dealt with as deaths would, as in the case of deaths generally, be more accurately recorded than live-births. It should be noted, however, that, quoting from the Madras Report, "it is probable, judging from the general conditions prevailing in the town, that this figure "(504) is much too low, and that a number of still-births are not recorded." Looking at the statement of births, on the lower half of page 31 of the report, there seems reason to doubt the sufficiency of the explanation given by the President of the cause of the high death-rate of Madras, which began in 1889 and has continued ever since. It is well known that scarcity produces a marked effect in reducing the birth-rate as well as in raising the death-rate; but the birth-rate, instead of declining in the years following 1889, has gone on increasing from a ratio of 35·3 per mille of population in 1888 to a ratio of 42·2 in 1895 and of 41·2 in the year under review. In no year subsequent to 1889 has it been under 36·8. But a high birth-rate, except under special circumstances, is accompanied by a high death-rate; and as the high birth-rate, which we have assumed to be a cause of the high death-rate, cannot be credited to scarcity, it is probable that improved registration may to some extent explain the high death-rate as well as the high birth-rate recorded since 1889. Moreover, the population of Madras is said to be rapidly increasing, and such increase since the taking of the Census of 1891 would have the effect of raising the ratios of both births and deaths above what those ratios would be if calculated on the increased, instead of on the census, population numbers.

3. The *deaths* numbered 17,131, and the mortality ratio, calculated on the Census figures of 1891, was 37·8 per thousand, whilst calculated on the estimated population for 1896 it was only 35·4. The chief causes of mortality were the same during the year under report as during its predecessor. Small-pox, measles, cholera, and bowel-complaints were rather more fatal than during the former year, whilst fewer deaths were credited to fevers.

4. Neither *small-pox* nor *cholera* was excessively fatal, the former having attributed to it 42 and the latter 97 deaths. Of those who died from small-pox, 28 were unvaccinated, seven were said to have been vaccinated, but showed no marks, whilst seven had been vaccinated. Amongst the unvaccinated the proportion of deaths to attacks was 35·4 per cent.; amongst those said to have been vaccinated, but had no marks of vaccination, 17·5; and amongst the vaccinated, 9·7. It is stated that, "out of the 75 unvaccinated who were attacked, 45 were not born in Madras, and nine "were under the age of compulsory vaccination." In a preceding paragraph the number of

unvaccinated who were attacked by small-pox is said to have been 79, perhaps this, and not 75, is the correct number. The ratio of mortality which the 42 deaths from small-pox give per mille of population is only 0·09. Although greater than the mortality for the preceding year, it is nevertheless inconsiderable, and a satisfactory proof of the efficiency of vaccination in Madras. Turning to Statement No. I., Appendix IV., which gives particulars of vaccination in the municipality, it is found that 18,789 successful primary vaccinations were performed during the official year 1896–97, and that 12,929 of these were performed on children under one year of age. The number of living children born in the calendar year 1896 was 18,684. If from this number we deduct the 5,570 deaths of children under one year of age in the same year, we have remaining available for vaccination 13,114. The number of children under one year of age who were successfully vaccinated having been, as already seen, 12,929, there would remain only the small number of 185 unvaccinated; and of these the majority, if not all, may have been found, owing to some form of illness, unfit to undergo vaccination. The quality of the primary vaccination, judging from the high percentage of 99·19 successful cases, could hardly be improved upon. Of re-vaccinations there were 7,828 cases, and of these 87·11 are recorded as having been successful. The number of successful primary vaccinations gives a ratio of 41·5 of the population protected against small-pox, which is slightly in excess of the ratio of births. In addition, 13·31 of every thousand of the population were successfully re-vaccinated. These figures seem to give a satisfactory explanation of the comparative immunity of the population of Madras from small-pox. Such results in a large native population could only be obtained by unremitting effort to enforce the provisions of the Vaccination Act, and it is no surprise to read that "the number of summonses taken out against parents and guardians for omitting to get "their children vaccinated after six months of age was 736." As a consequence of the proceedings taken, 521 of the children were vaccinated; whilst of the rest 48 were found unfit to be vaccinated owing to illness, 86 left the town, 66 prosecutions were withdrawn, seven of the parents or guardians were warned and discharged, and eight children died before the date posted for hearing in the Court. These details are worthy of record as showing that the law relating to vaccination in Madras City is neither allowed to become a dead letter nor administered in the half-hearted manner too common in many other towns in India. The total number of calves inoculated during the year was 638. Of these, six died from chills during the heavy rains of November and December, whilst six died "from "the effects of scarification for the manufacture of glycerized vaccine paste." A total of 12 calves thus died of the 638 used for supplying vaccine lymph. This contrasts very favourably with the mortality amongst the calves provided for the supply of lymph in Assam. In the latter province, of the 435 calves vaccinated during the same year, 20 died before the vesicles developed, and 75 after lymph had been taken from them. For every reason, too great care cannot be taken to prevent the deaths of the calves procured for vaccination purposes. Already there is great difficulty in obtaining a sufficient number; and, if once it gets about amongst the people that many of the calves operated on die at the vaccine depôts, this difficulty will not grow less. The cost of each successful case of vaccination, calculated on the net expenditure, was six annas, and, calculated on the gross expenditure, seven annas. This is high, but the work seems to be efficiently done, and the amount of protection conferred on the population of Madras to be well worth the outlay.

5. *Fevers* "continue to exact a heavy toll on the population, accounting for 6,039 deaths in 1896, "and a much larger number more or less incapacitated for work by sickness." The rise of fever mortality in the hottest part of the year is attributed to chill, the consequence of people sleeping in the open, often on damp ground and without sufficient covering to protect them from the wind. This conclusion is confirmed, it is said, by the fact that many of these cases are complicated by pneumonia. Until the sewerage of the town is effectively carried out, marked decrease in the prevalence of fevers is scarcely to be looked for.

6. Arrangements were made for dealing with *plague* should it break out in, or be imported into, the town; but, fortunately, although there were false reports of its appearance, no genuine case of the disease in either man or rats was reported up to the end of the year. Powers were obtained to enable the authorities to enforce "compulsory isolation, segregation, and disinfection." The practical experience gained in dealing with plague elsewhere, will have taught the need for applying these measures with caution should occasion for their application unfortunately arise. For keeping the plague from gaining a footing, the measures most likely to prove successful are the maintenance of scrupulous cleanliness throughout the town and the relief of overcrowding. For carrying out these measures Madras is in a better position than Bombay, which, besides having nearly twice the population to deal with, is confined within the limits of its island site.

7. *Sanitary Works.*—In the Government review of the report it is said :—"No substantial advance "was made during the year in the sanitary condition of the city; but many useful improvements "have been and are being carried out. The long contemplated scheme for the drainage of the city "has at last been sanctioned, and the Commissioners have undertaken the drainage of Mylapur to "start with." In one of the most insanitary and overcrowded parts of the city, arrangements have been made for laying out new streets. In carrying on the every-day work of conservancy the greatest difficulty is the want of scavengers. These leave their work to cultivate their fields when the rains come, and go to fairs and festivals, where they get higher wages and, no doubt, more congenial employment. It appears, also, that they have learnt the power which combination gives them, and not unfrequently strike work. The public, it is added, find even greater difficulty in obtaining the services of scavengers than the municipality. The application of coercive measures, which would seem to be contemplated under the title of a Labour Law, might not improbably be found to aggravate the trouble which such measures are intended to remedy. It is satisfactory to read that "much more stringency is observed in dealing with applications to build than was formerly the "case." The perpetuation of site-crowding, which constitutes one of the greatest sanitary evils large towns have to contend with, will thus receive a check. The Cooum River nuisance re-appears in every annual report, and is likely to continue to re-appear for many years to come. A scheme, which is estimated to cost 16 lakhs, and has for its object the improvement of the Madras water-supply, is under the consideration of Government.

8. Briefly, the sanitary history of the year was uneventful. The meteorological conditions were abnormal and the prices of food-grains high; but the influence of these factors in raising the death-rate was inappreciable. A birth-rate of 41·2 and a death-rate of 37·8 per thousand of population seem to indicate that the registration of vital statistics is closely supervised in Madras City. Neither from small-pox nor from cholera was the mortality high. That vaccination is efficiently carried out, the best proof is the low rate of mortality from small-pox. Infant vaccination receives special attention; and the provisions of the Vaccination Act are fully utilized to compel parents or guardians to have their children vaccinated within the period fixed by law. Vaccine lymph taken direct from the calf is used, and has given a high percentage of success. Arrangements were made with the object of dealing with plague, but fortunately this disease did not visit Madras. No substantial advance was made during the year in the sanitary condition of the city, but many useful improvements have been and are being carried out.

12th October 1898.

No. 15.

Memorandum of the Army Sanitary Commission on the Administration Report of the Municipal Commissioner of Bombay for 1896–97.

The year 1896 will be memorable for the outbreak in the City of Bombay of bubonic plague. The account given by the Health Officer of the circumstances connected with the first appearance of the disease, and of the measures taken with the purpose of endeavouring to stay its progress, fills the greater part of the Report.

2. The year was in many respects abnormal. The mean annual temperature was 80°, and the second highest on record in the last 51 years. The rainfall was 15 inches above the average; but instead of being distributed over four months it fell within a period of a little more than six weeks. Whilst the fall in June, July, and August largely exceeded the normal, that in September amounted to only 1·6 inches, instead of an average of 10 inches. High temperature, failure of crops, and a rise in the price of food stuffs to over 20 per cent., followed this abnormal monsoon. In his Report for 1893, the Health Officer wrote:—"It has been observed in the sanitary history of this city, that "whenever the season is abnormal, it is followed by a disturbance and an unwholesome state of "public health." In the year under report, scarcity combined with the abnormal nature of the season to produce an unfavourable influence on the public health and to raise the death-rate. Moreover, the scarcity outside Bombay drove numbers of famine-stricken or destitute people into the city, to increase the overcrowding and intensify the distress already prevailing.

3. The *birth-rate* of the year is very briefly dealt with: it did not differ greatly from that of the preceding year, having been 19·33 as compared with 19·08 in 1895. The Health Officer repeats the explanation formerly given of this low birth-rate and attributes it to the disproportion of males to females in the population. But the discovery in a single year by the vaccinators of 5,617 infants under one year of age whose births had not been registered, throws doubt on the sufficiency of this explanation and renders it probable that the low birth-rate is in part due to defective registration. If the latter explanation be accepted, the abnormally high ratio of still-born children in Bombay City would fall to something nearer to the ratio elsewhere prevailing. In the year under review, whilst the recorded number of live-births was 15,890, the number of still-births was 1,598. In coming to a conclusion different from that arrived at by the Health Officer it must not, however, be forgotten that, in the population of Bombay when the census of 1891 was taken, the males were in the proportion of 170·60 to every 100 females. Perhaps the question might be capable of settlement in the same way as a similar question of an abnormally low birth-rate, said to be due to the disparity of the sexes in the population, has been settled in Assam. In some of the towns of that province a census was taken of women of the child-bearing age, assumed to include those between 15 and 39 years, and the probable number of births calculated at the rate of 320 to every 1,000 women. The result was to show that the birth-rate so estimated was greatly higher than the rate calculated on the number of births registered. The table in the report showing the number of births and the birth-rate in each class of the population furnishes examples of violent contrasts. For instance, whilst the birth-rate recorded amongst Brahmans is only 9·18 per mille, and amongst Hindus of "other castes" who constitute more than half of the entire population only 16·73, it is 32·61 amongst low-caste Hindus and 34·45 amongst the Jewish community. Some explanation of the cause of these contrasts might be useful.

4. Exclusive of still-born, 33,451 deaths, equal to a ratio of 40·7 per thousand of population, were registered, being 8,370 more than in the previous year, and 8,267 more than the average. The fact that 19,582, or greatly more than half of those who died, were not born in Bombay, shows to what extent the death-rate of the city was affected by the great migration into it during the year of famine-stricken or destitute people in search of employment or food. A statement giving the number of deaths by months shows that in August there was a marked increase in the number of deaths, and that this increase was due, not to greater mortality amongst the permanent residents of Bombay, but entirely to greater mortality amongst those born elsewhere. Dr. Weir calls especial attention to this increase in the number of deaths in August having been limited to the classes of the population not born in the city, or, in other words, to the immigrant part of the population;

and argues therefrom that, either the increase in mortality was not due, as some would seem to believe, to bubonic plague already prevalent but not yet recognised, or, that if it was plague, the disease affected, not the people of Bombay, but only the classes born outside the city. The figures show that, whilst 1,157 persons born in Bombay died in July, only 1,134 of this class died in August. On the other hand, whilst 1,127 born elsewhere died in July, the number of deaths in this class had risen to 1,514 in August. The month of by far the highest mortality was December, during which 6,131 deaths were registered, or more than twice the number registered during any other month of the year.

5. The contrast between the death-rates of the different classes composing the population is as striking as that between their birth-rates. Amongst Jains the ratio of deaths per 1,000 was 62·83, and amongst low-caste Hindus 63·27 ; whilst that amongst Brahmans was 32·22 and amongst Hindus of other castes 35·77. The birth-rate recorded for Jains was only 15·50 per mille ; so that, if the registration is anywhere nearly accurate, we have a death-rate more than four times greater than the birth-rate. Likewise, as regards Brahmans, whilst their birth-rate is stated to have been 9·18, their death-rate was more than three times greater. As regards low-caste Hindus and Hindus of other castes, constituting between them more than half of the entire population, their death-rates are, in the case of the former somewhat less, and in the case of the latter somewhat more than double their birth-rates. If the births really stand in the proportion of 19·3 to 40·7 deaths, the population of Bombay, unless it were largely recruited from outside, would rapidly diminish and ultimately disappear. A high birth-rate, apart from special conditions, usually accompanies a correspondingly high death-rate ; but in Bombay there is an abnormally low birth-rate accompanying a high death-rate. The high death-rate of Bombay with its abnormally low birth-rate may therefore be taken to indicate a greater degree of unhealthiness than the same death-rate would indicate in a town with a normal birth-rate.

6. The causes of this high death-rate in Bombay City as a whole, and of the exceptionally high rate amongst particular classes of the population, are forcibly described by the Health Officer :— "Excluding the small communities liable to great fluctuations, the highest mortality has occurred "amongst Jains and Hindu low-castes. The high mortality amongst Jains has been greatly influenced "by the occurrence of bubonic plague in this community. The poorer classes of that community "live under very unfavourable sanitary conditions, in over-crowded, ill-ventilated rooms and shops. "Their manner of living is very poor, and a large number are scorbutic. The population is also a "very fluctuating one." As regards Hindu low-castes, Dr. Weir writes :—"Whenever the seasons "are unfavourable and prices of food are high the Hindu low-castes suffer most. They "are very poor, and they may often be seen searching amongst refuse for food. Their "dwellings are in the most crowded buildings of the most crowded localities. Several "families sleep in one room—a domesticity generally unknown amongst other classes. They "usually sleep on the floor on a thin sheet, and in the rainy season the ground on which "they sleep is damp and mouldy, and nearly as damp as the street outside." The Health Officer may well say that there can be on hope for the reduction of the high mortality in these classes until they are provided with more food and with dwellings suitable for human beings. Even when model *chawls* are built for their accommodation, Dr. Weir thinks there will be an inrush of the out-caste population from the country into the city, and that the consequent overcrowding will be difficult to combat. Perhaps under such circumstances the municipality might be justified in preventing the immigration of these swarms of destitutes, or in sending them back to the places whence they had come, seeing that their presence in excessive numbers in the city is productive of misery and a high mortality amongst themselves as well as serious danger to the health of the general population. The interests alike of the immigrants and of the citizens would seem to be served by some measure for limiting the influx of the former.

7. As compared with 1895, the year under report shows an increased mortality from all of the chief diseases. The 4 0 deaths recorded as due to *cholera* give a ratio of 0·60 per mille of population. As observed by Dr. Weir in former reports, the mortality from this disease was least at early periods of life, and increased with age. July and August were the months of greatest prevalence of cholera, 82 deaths having occurred in the former and 137 in the latter. "I ascribe the prevalence of the "disease in July," writes Dr. Weir, "to the abnormal season, and to the development of cholera "germs in the rainy season. A demonstration in favour of the probability of this conclusion is "given in the table showing the mortality in buildings by floors. That table shows that, out of "623 cases, as many as 367 occurred on ground floors amongst people living on damp ground." This differs from the theory usually held that cholera is a "water-borne" disease. However applicable Dr. Weir's theory of causation may be to Bombay, it would hardly account for the violent epidemics which prove so fatal in other parts of India at seasons when the country is parched by excessive heat. Comparing the ratios of deaths amongst those of the population using pipe water with the ratio amongst those using well water, the former is stated to be 78·25 and the latter 90·00. The important conclusion is drawn from the dates on which the first cases of the disease appeared in the different parts of the city, that "the cases did not proceed from district to district, but that they occurred "without regard to the position of the localities, or, in other words, that human communication was "not the condition that influenced the progress and spread of the disease."

8. From *small-pox* there were recorded 701 deaths. Of this number no fewer than 251 occurred amongst children under one year of age. From this the inference might be drawn that infant vaccination was neglected ; but if the return of vaccination on page 607 of the report is examined it will be seen that 13,474 children under one year of age were successfully vaccinated. Now, the total number of children born alive was only 15,890 ; whilst the number of deaths registered of children under one year was 7,273, leaving available for vaccination 8,617. It thus appears that, according to these figures, the number of infants vaccinated was nearly double the number available for vaccination. More than one explanation of this paradox might be suggested. The first that

occurs is defective registration and consequent failure to record a large proportion of the births. Another is the importation into the city of a number of newly-born children. It is known that many women of the native population leave their homes in cities to be confined in the country. In the Infectious Diseases Hospital, Arthur Road, 91 patients who had previously been vaccinated were treated for small-pox, and of these four died; in the same hospital 212 were treated who had not been vaccinated, and of these 68 died. Thus, of the vaccinated the deaths were almost exactly one to every 22 treated, and of the unvaccinated nearly one to every 3 treated.

9. *Fevers* were credited with 8,776 deaths, or 2,372 more than in the previous year. As was only to be expected from the description already given of their condition of life, the Jains and Hindus of low-castes suffered more severely than the other classes of the population. Whilst the ratio of deaths per mille of population for the entire city was 10·68, in the case of the Jains it was 18·15, and of the Hindus of low-castes 17·48.

10. As usual, *phthisis* was very destructive of life, and more especially of female life. Needless to say, "the sections of highest mortality from phthisis are the most overcrowded and ill-ventilated "sections of the city." Regarding the lamentable loss of female life, Dr. Weir writes:—"The "mortality of phthisis by sex shows the enormous loss of female life caused through seclusion "in crowded, ill-ventilated dwellings. The female mortality from phthisis is more than double "the male, and this excess of mortality falls chiefly on the Mussulman and high-class Hindu "female."

11. Of *bubonic plague* in Bombay there is an interesting account, illustrated by numerous diagrams and covering 159 pages. The history of the disease is carried into 1897. We can do no more here than touch a few of the points relating to the year under review. The existence of plague in the city was first recognised towards the end of September by Dr. Viegas. The preceding month was characterised by excessive rainfall. "The heavy rainfall in 1896, as we remember, flooded with "sewage the low-lying portions of the city, through which the polluted streams rushed in whirling "currents, leaving banks of mud and sludge behind to ferment or slowly dry; and moreover the "sewage flowed from the sewers on to the streets after each heavy downpour, and rushed up the "traps and flowed on to the low-lying ground. Unfortunately, in the beginning of the monsoon, a "serious obstruction occurred on the Worli foreshore, in the outfall channel of the sewage." The foregoing description is not dissimilar, as Dr. Weir observes, from that given by Gibbon of the events which preceded the pestilence from which Rome suffered towards the end of the sixth century. Regarding the immediate origin of the plague in Bombay there are many theories, but nothing is known with certainty. Whatever was the cause of the disease, the Health Officer makes it clear that the circumstances preceding its appearance were such as to favour an outbreak of sickness. Of these, the chief were the inundation of the low-lying parts of the city with sewage, and the influx of swarms of starving immigrants from the country, who added to the already existing overcrowding. Fever with glandular swellings was no new disease in Bombay, and the Health Officer says with regard to its recurrence in 1896, and the measures taken to prevent its spread:—"I believe we would have been as successful as at other times, had the rats "not been infected, and had the year not been abnormal, and food scarce and dear." This would seem to suggest belief in a local origin, as opposed to importation of the disease. The period preceding the outbreak was not only unhealthy as regards human beings, but is shown to have been marked by an increased mortality amongst the lower animals as well.

12. Immediately it became clear that genuine plague had to be dealt with, the utmost promptitude and energy were shown by the Health Department in the effort to stay its progress. One of the earliest measures adopted was the provision of an adequate staff for the purpose of searching out cases of the disease and having them promptly segregated. This measure excited much hostility and opposition among the people, as might have been expected by those conversant with the customs and caste prejudices of the natives, and its modification was soon found to be expedient. Another measure of great importance was the disinfection of buildings in which cases of plague had occurred. No less important was the emptying of infected buildings, and the opening up, when practicable, of such buildings to the action of light and air by removal of portions of their roofs and other suitable means. Stores of grain were exposed to the air, and when found to be unwholesome were destroyed. The panic amongst the inhabitants which followed the drastic remedies adopted by the authorities led to the flight of thousands from the city into the country, and to the importation of the disease into places hitherto free from it. There was a fear that the panic might extend to the scavengers, in which event the city would have become uninhabitable from the accumulation in it of the unremoved filth. But the fears of the people were somewhat allayed by the modification of the segregation rules, and the work of cleansing and disinfection continued to be vigorously prosecuted. "We treated houses practically as if they were on fire," writes Dr. Weir, "discharging into them "from steam engines and flushing pumps quantities of water charged with disinfectants."

13. Up to the end of the year the number of deaths recorded as due to plague was 1,936; but doubtless this only represents a part of the real number. In spite of the utmost vigilance of the medical and sanitary staff the concealment of cases of illness and of deaths was sure to take place when it became known that everyone suffering, or even suspected of suffering, from the disease would be removed to a hospital. The enormous increase in the death-rate during December is suggestive. The number of deaths recorded in November was 2,889: in December it was 6,131. This necessarily brief sketch may fittingly conclude with a quotation from the account of the epidemic given by the Health Officer:—"And yet an unprejudiced judgment on the progress of the "disease and the effect of the measures adopted to check it affirms the wisdom of all ages as handed "down to us, that the disease spreads most surely and rapidly where the overcrowding of buildings "on the ground surface is greatest, and where buildings are closest together and where least air and "light enter. A free current of air is most fatal to the growth of the bacillus in dwellings, and a

" wholesome body and a hopeful disposition most unfavourable to the growth of the disease in " human beings. In dwellings a pure atmosphere and in human beings a vigorous constitution are " the best allies against the pestilence. We have gained experience ; let us profit by it in the " future."

14. *Summary.*—The year was, from a meteorological point of view, abnormal : the temperature was higher than the average and the rainfall greatly in excess of normal. Whilst, ordinarily, the rainfall is distributed over four months, it was concentrated within little more than six weeks in 1896. The premature cessation of the rains was followed by crop failure and scarcity. The recorded birth-rate was slightly higher than it was in the preceding year, and less than half the death-rate, which was 40·7 per mille of population. The chief diseases were more fatal than in 1895 ; but cholera was credited with only 490 deaths and small-pox with 701. Although 251 deaths from small-pox occurred amongst children under one year of age, the number of infants successfully vaccinated, judging from the returns, was much in excess of the number available for vaccination, estimating this number by deducting the number of deaths amongst children under one year of age from the recorded number of births. The high rate of mortality from phthisis may be taken as one of the indications of the overcrowding and defective ventilation of the dwellings in which the victims of the disease resided ; whilst the excessive mortality caused by it amongst females illustrates the baneful effects of the seclusion in close rooms to which, more especially, Mussulman and high-caste Hindu women are subjected. Fevers were unusually fatal, a fact which may suggest incomplete registration of deaths from bubonic plague. This last disease was first definitely recognised towards the end of September, and, in spite of the most vigorous measures adopted to stay its progress, continued to spread in the City of Bombay during the rest of the year. Moreover, the panic which followed the enforcement of segregation caused an exodus of thousands of the inhabitants into the country and the importation of disease into other towns by the fugitives.

SALE OF GOVERNMENT PUBLICATIONS.

The under-mentioned Firms have been appointed sole Agents for the sale of Government Publications, including Parliamentary Reports and Papers, Acts of Parliament, Record Office Publications, &c., &c., and all such works can be purchased from them either directly or through retail booksellers, who are entitled to a discount of 25 per cent. from the selling prices :—

IN ENGLAND :—

For all publications *excepting* Ordnance and Geological Maps, the Hydrographical Works of the Admiralty and Patent Office Publications :—MESSRS. EYRE AND SPOTTISWOODE, East Harding Street, E.C.

For Geological Maps :—Mr. E. STANFORD, Cockspur Street, S.W.

For Hydrographical Works of the Admiralty :—Mr. J. D. POTTER, 31, Poultry, E.C.

Patent Office Publications are sold at the Patent Office.

For all publications *excepting* the Hydrographical Works of the Admiralty and Patent Office Publications.

IN SCOTLAND :—MESSRS. JOHN MENZIES & Co., 12, Hanover Street, Edinburgh, and 90, West Nile Street, Glasgow.

IN IRELAND :—MESSRS. HODGES, FIGGIS, & Co., LIMITED, 104, Grafton Street, Dublin.

ORDNANCE SURVEY MAPS OF GREAT BRITAIN AND IRELAND :—There are Agents for the sale of these Maps in most of the chief towns. Copies can also be ordered at many Head Post Offices, and through any Bookseller, or from the Director-General Ordnance Survey, Southampton ; or, in the case of Ireland, from the Officer in Charge Ordnance Survey, Dublin.

The following is a list of some of the more important Parliamentary and Official Publications recently issued :—

Parliamentary:

Statutes—

Public General, Session 1899. With Index, Tables, &c., &c. Roy. 8vo. Cloth. Price 3*s.*

Second Revised Edition. By authority. A.D. 1235–1713 to A.D. 1872–1880. XIV. Vols. Price 7*s.* 6*d.* each.

Revised Editions. Tables showing subsequent Repeals, effected by Acts of 61 & 62 Vict. 1898. Price 6*d.*

Statutes in Force. Chronological Table of and Index to. 14th Edition. To end of 61 & 62 Vict. 2 vols. Price 10*s.* 6*d.*

The Statutory Rules and Orders revised. Statutory Rules and Orders, other than those of a local, personal, or temporary character, issued prior to 1890, and now in force. Vols. I. to VIII. Price 10*s.* each.

Statutory Rules and Orders other than those of a Local, Personal, or Temporary Character. With a List of the more important Statutory Orders of a Local Character arranged in classes ; and an Index. Roy. 8vo. Boards. Issued in the years 1890, 1891, 1892, 1893, 1894, 1895, 1896, 1897, and 1898. Price 10*s.* each.

Statutory Rules and Orders in force on 1st January 1898. Index to. Imp. 8vo. Cloth. Price 10*s.*

Statutory Rules and Orders, 1899. Registered under the Rules Publication Act, 1893. In course of issue.

Acts of Parliament, Public and Local and Private, Session 1899. In course of issue.

[C. 9509.] DANGEROUS TRADES. Fifth and Final Report of Departmental Committee. Price 5*d.*

[C. 9526.] LEAD COMPOUNDS IN POTTERY IN FRANCE. Report on. Price 2½*d.*

[C. 9379.] LIQUOR LICENSING LAWS. Reports of Royal Commissioners on. Price 3*s.* 3*d.*

[C. 9523.] LOCAL TAXATION. Royal Commission Memorandum chiefly relating to the Classification and Incidence of Imperial and Local Taxes. Price 2*s.*

[C. 9485.] RAILWAY ACCIDENTS (U.K.). General Report. 1898. Price 3½*d.*

[C. 9457.] RAILWAYS (U.K.). General Report in regard to Share and Loan Capital. 1898. Price 4½*d.*

[C. 9506.] SAMOA. Joint Commission on. Correspondence and Report of the. Price 3*d.*

[C. 9359.] SCIENCE AND ART DIRECTORY. Revised to July, 1899. Price 6*d.*

[C. 9182.] STATISTICAL ABSTRACT FOR FOREIGN COUNTRIES. Years 1887 to 1896-7. 25th No. Price 1*s.* 6*d.*

[C. 9458.] STATISTICAL ABSTRACT FOR THE UNITED KINGDOM. Years 1884 to 1898. Price 1*s.* 1*d.*

MINES. Reports of H.M. Inspectors for 1898, with Summaries of the Statistical portion under the provisions of the Coal Mines Regulation Act, 1887 ; Metalliferous Mines Regulation Acts, 1872–1875 ; Slate Mines (Gunpowder) Act, 1882, Districts Nos. 1 to 13. Set complete Price 7*s.* 1*d.*

MINES in the United Kingdom and the Isle of Man. List of, for 1898. Price 3*s.*

QUARRIES. Do. do. do. 1898. Price 3*s.* 8*d.*

MINES ABANDONED. List of the Plans of. Corrected to 31st December 1898. Price 10*d.*

The following appear periodically, and can be subscribed for :—

TRADE OF THE UNITED KINGDOM WITH BRITISH POSSESSIONS AND FOREIGN COUNTRIES, showing the Quantities and the Declared Value of the Articles.

TRADE REPORTS of the British Colonies, with information relative to population and general condition.

TRADE REPORTS by Her Majesty's Representatives in Foreign Countries, and Reports on Commercial and General Interests.

The Proceedings of Parliament in public and private business, published daily. House of Lords, Price 1*d.* per 4 pp. ; House of Commons, 1*d.* per 8 pp.

State Trials, being Reports of the Chief State Trials which have taken place between 1820 and the present time, published under the supervision of a Committee appointed by the Lord Chancellor. Roy. 8vo. Half cloth. 1820–1823 to 1850–1858. 8 vols. Price 10*s.* each.

A. GODLEY,
Under Secretary of State for India.

INDIA OFFICE,
October, 1899.

REPORT.

The present Report on Sanitary Measures in India during the year 1897 is prepared for presentation to Parliament. It contains chapters on the health of the European and Native troops, on the health of prisoners in jails, and on the health of the general population ; it also contains chapters on vaccination, on medical institutions, including medical schools and lunatic asylums, and a chapter on sanitary works. Appended to the Report are abstracts of reports by the three principal Sanitary Commissioners in India, and memoranda by the Army Sanitary Commission in England reviewing the several Sanitary Reports for India.

I.—EUROPEAN ARMY.

Sickness and mortality in 1897.

The health of the European troops on service in India in 1897 was not so good as in the previous year. On an average strength of 68,395, the admissions into hospital were in the ratio of 1,557 per 1,000, against 1,387 in 1896, the daily sick-rate rose from 94 to 101, and the death-rate from 14·84 to 22·93. The invaliding ratio (33) was higher by 5 per 1,000, so that the total loss by death and invaliding was equal to 56 per 1,000, an increase of 13 per 1,000 on the previous year.

The Presidential Army system was abolished in 1894, and the whole of the forces in India is now designated the Army of India, divided into the Bengal, Punjab, Madras, and Bombay Commands. This organization took effect from the 1st April 1897.

The following statement shows the relative extent of sickness and mortality among European troops in the four Commands during 1897 and the previous year :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.				
			Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
Bengal	1897	20,113	1,619	113	23·32	41	64
	1896	22,457	1,436	100	18·70	29	48
Punjab	1897	17,190	1,460	93	21·52	22	44
	1896	18,823	1,282	84	13·60	26	40
Madras	1897	12,369	1,354	104	13·10	48	61
	1896	13,488	1,336	99	9·79	33	43
Bombay ...	1897	14,859	1,508	92	14·33	32	46
	1896	15,716	1,485	92	15·14	24	39
INDIA ...	1897	68,395	1,557	101	22·93	33	56
	1896	70,484	1,387	94	14·84	28	43

It will be seen from the above statement that of the four Commands Bengal had the highest daily sick and death rates. The Madras Command was again the healthiest, and its death-rate was not much more than half that of Bengal.

The chief causes of sickness in the whole European Army were, as in the year 1896, venereal diseases and ague, the former yielding a ratio of 486 per 1,000 against 512 in 1896, and the latter 395 per 1,000 against 239. More than half (56 per cent.) of the total sickness resulted from these two causes. Enteric fever, as usual, was the chief cause of mortality, and the death-rate from it was 9·01 per 1,000 against 6·31 in 1896. This fever yielded over 39 per cent. of the total deaths.

Groups of stations.

The following table shows the sickness and mortality among the European troops according to groups :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,202	1,474	117	11·65
Burma, Inland	2,678	1,512	106	10·83
Bengal and Orissa	2,269	1,501	95	19·39
Gangetic Plain and Chutia-Nagpur	6,833	1,513	108	25·17
Upper Sub-Himalayan	13,508	1,504	100	18·21
North-Western Frontier, Indus Valley, and North-Western Rajputana.	4,983	1,782	104	24·48
South-Eastern Rajputana, Central India, and Gujarat.	6,150	1,959	128	33·01
Deccan	8,865	1,457	101	13·99
Western Coast	1,471	1,154	77	11·56
Southern India	3,177	1,393	94	15·11
Hill Stations	7,058	1,245	98	14·17
Hill Convalescent Depôts	3,156	1,138	88	14·89

Of the above 12 groups, five returned a higher daily sick-rate than the ratio for the whole European Army, the highest being 128 per 1,000 of average strength in South-Eastern Rajputana, Central India, and Gujarat group. The Burma Coast group came next with a ratio of 117, followed by the Gangetic Plain and Chutia-Nagpur and Burma Island groups with ratios of 108 and 106 respectively. The lowest ratio (77) was returned by the Western Coast group. The death-rate of the entire Army was exceeded by three groups, viz., South-Eastern Rajputana, &c., the Gangetic Plain and Chutia-Nagpur, and the North-Western Frontier, Indus Valley, and North Western Rajputana groups.

Of the stations with a strength of over 1,000, five returned death-rates above 20 per 1,000, viz., Agra 57·90, Peshawar 46·24, Meerut 24·45, Mhow 23·00, and Umballa 22·75.

Cholera.

The mortality from cholera in the European Army was higher than in 1896. The admissions to hospital from the disease numbered 117 or 1·7 per 1,000 of average strength, against 70 or 1·0 per 1,000 in 1896, and the deaths rose from 63 or 0·89 per 1,000 to 80 or 1·17.

Small-pox.

Among the whole of the European troops in India there were during the year under notice only 24 cases of small-pox ; of these four were fatal. In the previous year there were 122 cases and ten deaths.

Fevers.

From intermittent fever the admissions to hospital among the European troops in 1897 were in the ratio of 395 per 1,000 of strength, against 239 in the previous year. The death-rate under this head was 0·41 per 1,000, against 0·10 in 1896.

From enteric fever the admissions rose from 1,795 or 25·5 per 1,000 of strength to 2,214 or 32·4, and the deaths from 445 or 6·31 per 1,000 to 616 or 9·01. Of the four Commands Punjab recorded the highest mortality under this head, viz., 11·05, followed by Bengal with a ratio of 10·39, Bombay 6·46, and Madras 4·93. Among the larger stations with an average strength of over 1,000, Agra returned a death-rate from this fever of 45·04, Peshawar 26·93, Meerut 18·58, Mhow 16·95, Umballa 15·32, Allahabad 14·34, and Lucknow 11·93, and in four other stations the ratios ranged from 8·77 to 6·60. As usual, young and unacclimatised soldiers were the chief sufferers ; among those from 20 to 25 years of age the death-rate was 12·74 per 1,000 against 9·52 in 1896, while among men between 25 and 30, and from 30 to 34, the mortality was 4·98 and 2·77 per 1,000 respectively. Among men of less than one year's residence in India

the death-rate from this fever was 18·50 per 1,000, among men between one and two years 10·79, and among troops between five and ten years' service the rate was 2·98 per 1,000.

Bowel complaints.

The admissions from dysentery and diarrhœa among the European troops were in the ratio of 79 per 1,000 of strength, or 33 per 1,000 more than in 1896. The mortality from dysentery was in the ratio of 2·53, and from diarrhœa 0·23 per 1,000. Dysentery was most prevalent in the Madras Command.

Plague.

There were five cases of plague among the European troops in 1897, but none of them were fatal.

Venereal diseases.

Venereal diseases, as usual, came first in the list of causes of admission to hospital; and also in the causes of invaliding. They were the cause of 31 per cent. of the total sickness during 1896, and over 29 per cent. of the invaliding of the European Army of India. The ratio of admissions from venereal diseases per 1,000 of strength was 485·7 or 25·9 below that of 1896. Dr. Harvey, Sanitary Commissioner with the Government of India, states that this reduction appears to have been connected with the employment of a large number of men on field service in the second half of the year, as the number of venereal admissions was much lower from July to December than from January to June. In spite, however, of the fall in the general ratios in 1896 and 1897, the admission-rate from secondary syphilis continued to rise, and in the year under notice reached 101·9 per 1,000, being the highest on record. The admission-rate from venereal diseases was highest in the Bengal Command, viz., 600 per 1,000, next came Madras with a ratio of 542, Bombay with 475, and the Punjab with 404, but only in Bombay was there a decrease. The number of men constantly sick in hospital from these diseases was 2,992, against 3,162 in the previous year, being equivalent to about three regiments; and the average stay of a case in hospital was 33 days. "Such figures," the Army Sanitary Commission state, "may be left to tell their own tale. Those who are not convinced by them of the "alarming ravages of venereal disease amongst our young soldiers, and of the urgent need "for the adoption of effectual measures for holding it in check, would not be convinced "by any description of the physical ruin it inflicts on its victims and on their posterity. "A visit to the wards of the Netley Hospital might help to dispel the doubts of those "who still continue to regard with scepticism the official figures showing the havoc "annually wrought by venereal disease amongst the soldiers of the European Army of "India." The deaths from these diseases numbered 23, and the invalidings 662, against 14 and 479 respectively in 1896.

Invaliding.

The loss to the whole army by invaliding during 1897 amounted to 2,258 men, equal to 33·01 per 1,000, against 1,966 or 27·89 in 1896. The proportion of invalids to strength was highest in the Madras Command (47·5), followed by Bengal (40·9), Bombay (31·8), and Punjab (21·9). Of the total number invalided, 34 per cent. were discharged as unfit for further service, being 5 per 1,000 lower than in 1896. As regards the influence of age and length of residence in India upon invaliding, 63 per cent. of the total number invalided were under 25 years of age, against 62 in 1896, while 32 per cent. were of less than two years' service, and 85 per cent. were of less than five years' service. In the European Army as a whole 84 per cent. of the total strength had seen less than five years' service.

II.—NATIVE ARMY.

Sickness and mortality in 1897.

There was more sickness and greater mortality in the Native Army of India during 1897 than in 1896, which is attributed to an increase of malaria owing to an abundant monsoon after a long period of drought.

The ratios of sickness and mortality among Native troops in the six Commands during 1897 and the previous year are given in the following table :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.		
			Admissions.	Daily Sick.	Deaths.
Bengal	1897	26,644	834	33	9·12
	1896	26,279	809	31	8·52
Punjab	1897	35,454	867	31	13·26
	1896	38,824	766	29	14·37
Madras	1897	23,588	710	32	9·45
	1896	25,009	665	31	8·04
Bombay	1897	26,421	822	27	10·48
	1896	24,707	880	28	8·82
Corps of Central India and Rajputana*	1896	5,062	630	20	10·47
Hyderabad Contingent	1897	6,554	551	19	6·26
	1896	6,970	563	19	7·03
INDIA	1897	129,802	839	32	13·12
	1896	128,826	763	29	10·20

* Since 1896 these corps have been distributed between and absorbed into the Bengal and Bombay Commands.

Of the five Commands the Punjab again returned the highest rate of mortality, though the figures show an improvement on those of 1896. Pneumonia was very prevalent in this force, and the death-rate from it was 4·29 per 1,000, or about a third of the total mortality.

The chief cause of sickness in the Native Army was ague, which caused 41 per cent. of the total admissions. Among the diseases from which the admissions to hospital were higher than in 1896 were enteric fever, dysentery, and ague ; while from influenza, small-pox, scurvy, cholera, and respiratory diseases there was a decrease in the admissions. There was considerably less influenza among the Native troops in 1897 than in the previous year, and the admission-rate fell from 10·7 per 1,000 of average strength in 1896 to 5·4. From venereal diseases the admission-rate in the Native Army was only 40·8 per 1,000 of strength, as compared with 485·7 per 1,000 among European troops. Figures under this head are not available for the years before 1877. The ratios run at a much lower level than those of European troops, and there is not the same tendency to increase. Only twice since 1877 has the ratio reached 40 per 1,000, viz., in 1890, when the admission-rate was 41·1, and in the year under notice.

Respiratory diseases were the chief causes of death in the Native Army, and no less than 24 per cent. of the total deaths were due to them. The death-rate under this head was 3·23 per 1,000 of average strength, against 3·72 in 1896. From pneumonia alone the mortality among the Native soldiers (2·73 per 1,000) was nearly five times as great as that among European troops (0·60 per 1,000). Fevers of all kinds were the cause of 14 per cent. of the total deaths, against 44 per cent. among the European troops. From ague, remittent and simple continued fevers, the deaths among the Native troops were in the ratio of 1·72 per 1,000, while among the European troops the proportion was 1·02.

On the other hand, the death-rate from enteric fever among the Native troops was only 0·12 per 1,000, as compared with 9·01 among the European troops. From cholera there were 68 deaths in the Native Army, equal to 0·52 per 1,000 of strength, as compared with 88 and 0·69 respectively in 1896.

During 1897 there were 131 cases of plague among the Native troops with 81 deaths, against 2 cases and 1 death in 1896.

The following statement gives the principal statistics of the Native Army arranged in geographical groups for 1897 :— **Groups of stations.**

——	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	2,215	690	29	4·51
Burma, Inland	5,354	784	37	7·47
Assam	1,791	1,066	45	12·84
Bengal and Orissa	3,059	935	38	6·21
Gangetic Plain and Chutia-Nagpur	6,295	618	27	9·53
Upper Sub-Himalayan	14,704	697	27	8·43
North-Western Frontier, Indus Valley, and North-Western Rajputana.	15,270	1,132	35	13·56
South-Eastern Rajputana, Central India, and Gujarat.	12,203	784	28	7·38
Deccan	19,137	729	26	12·75
Western Coast	2,808	760	32	8·55
Southern India	8,229	612	33	9·36
Hill Stations	20,430	973	37	14·39

In five of the above groups the daily sick-rate was lower than that for the whole Native Army, and in two the mortality was greater. The highest mortality was that of the Hill Stations group (14·39), which shows an increase of 4·14 per 1,000 on the rate for the previous year.

Of the large stations with a strength of over 1,000, the following recorded the highest death-rates: Belgam 34·31, Dharmsala 25·60, Edwardesabad 24·78, Poona 21·05, and Dehra Dun 20·75.

III.—GENERAL POPULATION.

The year 1897 was a trying one from a health point of view. Failure of the rains of 1896 led to scarcity and famine, the effects of which told severely on the poorer classes, and resulted in most provinces in a diminished birth-rate and a high death-rate. Great anxiety was also occasioned by the plague, which happily was confined chiefly to the Bombay Presidency.

Vital statistics.

Births were registered throughout all the 10 provinces in India in 1896, and the birth-rates varied between 42·6 and 20·24 per 1,000 of population under registration. The best results were obtained in the Punjab, Berar, Bengal, Bombay, Assam, Lower Burma, and the North-Western Provinces and Oudh, their respective rates being 42·6, 39·7, 36·9, 33·5, 32·6, 31·8, and 31·1. In the remaining provinces the birth-rates ranged between 28·7 in Madras and 20·2 in Coorg. Berar was the only province which recorded a higher birth-rate than in the previous year. The birth-rates exceeded the death-rates in four provinces, the excess per 1,000 varying between 11·5 in the Punjab and 3·3 in Madras. The recorded deaths rose from 6,779,016 or 32·05 per 1,000 of registered population in 1895 to 7,645,257 or 36·03. With the exception of Bengal and the Punjab, the mortality recorded in the several provinces was higher than in 1896. Of the chief diseases, cholera was much more prevalent, and the total number of deaths from it rose from 469,667 to 550,768. The increase was spread over six of the provinces, but Assam, the Central Provinces, and Madras were the chief sufferers, their death-rates from this cause being 6·62, 6·01, and 4·4 per 1,000 respectively, against 3·39, 5·58, and 1·5 in 1896. There was an increase also in the deaths from fevers, which was participated in by all the provinces except Bengal. In connexion with this cause of death the scheme for the sale of quinine at a low price by postal agency continued to make steady progress. The mortality from dysentery and diarrhœa was considerably higher than in the previous year ; and from small-pox there was an increase of 27,275 deaths.

The deaths from the chief diseases and from all causes in the several provinces were as follow :—

	Cholera.		Small-pox.		Fevers.		Dysentery and Diarrhœa.		Deaths from all Causes.		
	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000 of Population under registration.	
										1897.	1896.

Bengal.

The year 1897 in Bengal was on the whole healthy, notwithstanding the prevalence of scarcity and famine. The number of births registered in the province fell from 2,703,486 or 38·03 per 1,000 of population in 1896 to 2,625,844 or 36·94, the latter being made up of district rates varying from 47·40 in Malda to 28·97 in Pabna and 18·46 in Calcutta. The decrease in the provincial birth-rate, Dr. Dyson, the Sanitary Commissioner, attributes to the scarcity which prevailed from October 1896 to September 1897, and which lowered the vitality of the people and reduced their fecundity. Of the 46 districts there was an

increase of births in 19, the greatest advance being in Balasore, where the ratio was 8·61 per 1,000 in excess of the previous year. Purnea followed with an increase of 6·45, 24-Parganas of 5·68, Jessore of 5·55, and Malda of 5·06. Out of 147 towns only 11 returned a birth-rate in excess of 40 per 1,000, while 17 rural areas returned rates of over 50 per 1,000, and 65 others over 45 per 1,000.

The total number of deaths registered during the year under notice was 2,341,632 or 32·94 per 1,000, as compared with 2,428,830 or 34·17 in 1896. There was thus an excess of births over deaths of 284,212 or 4·0 per 1,000. The district death-rates ranged from 49·46 in Chittagong to 23·88 in Singhbhum. In urban areas the rate of mortality fell from 36·14 to 35·09, which was made up of ratios varying from 89·59 in the small municipality of Bhadreswar in Hooghly to 14·20 in the municipality of Maniktola in the 24-Parganas. Twelve out of the 147 towns returned a death-rate in excess of 50 per 1,000, and 18 in excess of 40 per 1,000, while 24 returned rates below 25 per 1,000. In rural areas the death-rate fell from 34·07 to 32·83. Chakaria in Chittagong district returned the enormously high death-rate of 152·94, which was due to 5,377 people having perished during the cyclone of 24th October.

Of the chief death causes cholera was again widely prevalent in 1897, but the number of deaths registered from it fell from 226,824, or 3·19 per 1,000, in 1896 to 196,247 or 2·76. Every district was affected by the disease, but the mortality varied greatly, and the number of villages attacked was 29,776, or 13·26 per cent. of the total, against 27,460 or 12·23 per cent. in 1896. Nine districts recorded cholera death-rates of over 5 per 1,000, viz., Puri (9·57), Chittagong (8·35), Lohardaga (8·02), Manbhum (7·00), Palamau (6·61), Cuttack (5·86), Hazaribagh (5·48), Backergunge (5·24), and Faridpur (5·18) ; in 20 other districts the rates ranged from 4·88 to 2·08, and in eight districts the rates were below 1 per 1,000. As regards the seasonal incidence of the disease in each of the main geographical divisions of the province, the seasons of highest mortality in Bengal proper were April, March, and June ; in Behar the rates were highest in August, June, and July ; in Orissa during July, June, November, and August ; and in Chota Nagpur in August, July, September, and June.

From small-pox the mortality was much higher than in 1896, the number of deaths having risen from 13,388 or 0·19 per 1,000 to 19,655 or 0·27 in 1897, or by nearly 50 per cent., an insignificant rate, however, when compared with those from other diseases prevalent in Bengal. The disease was present in all the districts except Jalpaiguri, but the only districts in which it can be said to have prevailed in an epidemic form are Shahabad (1·97), Puri (1·95), and Gaya (1·21). The prevalence of the disease in Shahabad was attributed to the large number of unprotected labourers who came to the district during the famine in search of work ; and in Puri infection was said to have come from the adjoining district of Ganjam in Madras Presidency.

About three-fourths of the total deaths were recorded under fever, a term which "covers a multitude of complaints in the minds of the village chaukidar, who is primarily "responsible for registration, and it is certain that numerous deaths are put down to "fever which are really due to other causes." Still, there is no doubt that fever claims more deaths than any other disease. The number of deaths reported to have occurred from fever during the year was 1,679,132 or 23·62 per 1,000 of population, against 1,760,225 or 24·76 in 1896. Out of the 46 districts, 22 recorded a higher fever mortality than the provincial rate, six registering a rate over 30 per 1,000, Pabna and Hazaribagh coming first with rates of 35·57 and 35·26 respectively. The high rate of Pabna was attributed to the scanty rainfall, and to the filthy and stagnant ditches and the Tarai tracts with which the district abounds. In Hazaribagh malarial fever is reported to have prevailed considerably in September, "when for a few weeks throughout the district it was very "widespread, more so than in most years, and rendered very fatal by the debilitated "condition of the people, owing to the many months of privation they had passed through, "unwholesome jungle produce chiefly forming the food of large numbers during the late "famine."

From dysentery and diarrhœa 53,822 deaths were registered, equal to 0·75 per 1,000 of population, against 47,935 or 0·67 in the previous year. Of the districts, Lohardaga returned the highest death-rate from these causes (4·96), Calcutta came next (4·72), followed by Puri (4·08), Howrah (3·97), and Darjeeling (3·86). With the exception of Lohardaga these districts have headed the list, though in a different order, for the last four years. The increase in mortality under this head was, it is said, almost solely due to the prevailing scarcity among the poorer classes, who were "obliged to live on herbs, "roots, leaves of trees, and other unsuitable and unwholesome food."

In Calcutta the birth-rate was identically the same as in 1896, viz., 18·46 and 18·49, and there was but little difference in the death-rate, that for 1897 being 36·18, as compared with 35·73 in the previous year. There was an increase in mortality under all the chief death causes except cholera, from which the deaths fell from 3,449 to 2,349. Five hundred and sixty-three anti-choleraic inoculations by M. Haffkine's method were performed during the first three months of 1897, after which the Corporation discontinued the grant for this purpose. There were 161 deaths from small-pox, as compared with 69 in 1896. It is noteworthy that during the last three months of the year the town was absolutely free from small-pox. The deaths from fever rose from 9,564 in 1896 to 9,619, the death-rates (14·0) being the same in both years. From dysentery and diarrhœa the deaths also rose from 2,967 in 1896 to 3,218 in 1897.

North-Western Provinces and Oudh.

The exceptional conditions of the year in consequence of the scarcity and distress which prevailed in certain parts of the North-Western Provinces and Oudh are strongly reflected in the vital statistics. "The year now closed," the Sanitary Commissioner (Dr. Thomson) writes, "has been one of exceptional trial. It is a history of patient and quiet endurance "on the part of the people, and of much anxious work on the part of those entrusted with "the care of their welfare. The mortality, though far below what might have been "reasonably expected, has been, in the nature of things, high." In addition to famine plague effected an entrance into the province in April, but prompt measures were taken to prevent the disease securing a permanent footing, and only 73 deaths were reported.

During the year 1,458,947 births were recorded, giving a ratio of 31·10 per 1,000 of population, as compared with 1,660,387 or 35·40 in 1896. Of the total 48 districts 22 showed a birth-rate above and 26 below the average of the provinces. Bulandshahr headed the districts with a birth-rate of 50·74, followed by Etah 47·48, Aligarh 46·02, Muzaffarnagar 43·73, Meerut 41·78, and Bareilly 41·35. The birth-rate in municipalities was 34·77 against 39·30 in the previous year, and was made up of extremes ranging from 51·96 in Kandhla to 9·56 in Naini Tal.

The number of deaths registered rose from 1,562,894 or 33·32 per 1,000 of population in 1896 to 1,897,592 or 40·46, and exceeded the births by 438,645 or 9·36 per 1,000. The provincial death-rate, which was made up of district rates ranging from 62·07 in Hamirpur to 23·67 in Garhwal, was exceeded in 25 districts. The death-rate in municipalities was 49·01 against 40·73 in 1896. In several municipalities the rate of mortality was considerably above the average; but this was mainly due to the municipalities being "the situation of poor-houses, to which the beggars, lepers, and the generally submerged "portion of the population came too frequently only to die." Out of 104 municipalities 76 recorded more deaths than births. Registration was again tested by local authorities, and the results disclosed an omission of 2·79 per cent. on 148,015 births, and 2·43 on 179,149 deaths; and in cases tested by the Vaccination Department the omitted percentages were 0·84 of births and 0·62 of deaths.

Of the chief diseases, cholera was less fatal by 24,939 cases than in 1896, the total deaths from the disease numbering 44,208 or 0·94 per 1,000, as compared with 69,147 or 1·47. Though the mortality was above the average in some districts, there were no excessive ratios, and three districts were free from the disease. Pilibhit recorded the highest district rate of 3·21, followed by Jalaun 3·03, Hamirpur 2·86, Banda 2·72, and Sitapur 2·16. The reduced mortality under this head is the more satisfactory, as from the accumulation of large bodies of workers on famine relief work an increase might have been expected. More deaths from cholera were recorded in August than in any other month, the number reaching 7,978, closely followed by 7,534 in July, and 7,317 in June. The disease declined with the cold weather, and in December 797 deaths were reported. All the large fairs in the province passed off without the appearance of epidemic disease.

From small-pox the mortality was more than double that of the previous year, the deaths reaching 87,127 or 1·86 per 1,000, against 42,771 or 0·91 in 1896. The epidemic was widespread in character, and the explanation for its increase "is possibly to be found "in the peculiar climatic conditions of the year." Famine districts were not particularly affected. In Sultanpur district, where the death-rate was highest (5·98), the rural circles have shown for some years past a very low percentage of vaccinations; and Jaunpur, which recorded the next highest rate (5·57), is also said to be badly protected. Bijnor came next with a ratio of 5·32, followed by Budaun, Partabgarh, Rae Bareli, Hardoi, and Mirzapur with ratios of over 4 per 1,000.

To fevers were ascribed 77 per cent. of the total deaths. The mortality from fever in 1897 was much higher than in the previous year, the number of deaths having risen

from 1,205,964 or 25·71 per 1,000 to 1,463,716 or 31·21. Among the districts, Bareilly came first with a fever death-rate of 48·65, followed by Hamirpur 48·11, Jalaun 47·85, Agra 46·72, Pilibhit 42·63, Hardoi 40·73, and Lucknow 40·61. Five other districts recorded ratios above the provincial rate. The mortality reached its maximum in October and the minimum was in June. Dr. Thomson remarks that in a year like 1897 it is impossible to dissociate fever and famine as factors affecting the death-rate, and that it is unsafe to definitely say more than that malarial fever was of a severe type, and that the people generally were, from a reduced condition of health, less able than usual to withstand it.

The deaths from dysentery and diarrhœa during 1897 numbered 58,822, an increase of 17,964 on the mortality of the previous year, the death-rates being 1·25 and 0·97 respectively. Among districts, Garhwal recorded the highest ratio of 5·91, followed by Banda 4·69, Fatehpur 4·39, Jhansi 4·36, and Almora 3·82. "Excepting the hill tracts," Dr. Thomson states, "which always show large ratios from these diseases, the explana-" tion no doubt lies in the exposure necessarily attendant on the congregation of large " bodies of workers on relief works."

Punjab.

Notwithstanding the prevalence of scarcity and an outbreak of plague, the year 1897 in the Punjab was on the whole a healthy one. The number of births registered was 874,623 or 42·6 per 1,000 of population, as compared with 884,692 or 43·04 in 1896. The birth-rate was again higher than that of any other province in India, and was made up of district ratios ranging from 57·5 in Jhang to 19·3 in Simla and 30·5 in Peshawar. Further improvement was made in the registration of births in the frontier districts, except in Peshawar and Hazara. The provincial birth-rate exceeded the death-rate by 11·6 per 1,000 of population, and in ten districts the excess was considerable, ranging between 25·3 and 15·0 per 1,000; while there were only three districts (Hissar, Dera Ismail Khan, and Simla) in which the deaths exceeded the births.

From all causes 638,227 deaths were registered during the year, giving a death-rate of 31·05 per 1,000, against 648,099 or 31·53 in 1896. The highest district rates were reported from Dera Ismail Khan 50·18, Hissar 45·31, Muzaffargarh 44·25, Bannu 43·03, Karnal 40·83, and Jhang 40·37, the remainder varying between 37·36 in Gurgaon and 21·89 in Gujrat. With the exception of the outbreak of plague noticed below, no disease of an unusual character prevailed, and there was a marked diminution in the mortality from cholera and small-pox.

The province suffered very little from cholera, only 622 deaths from this cause having been recorded as compared with 5,146 or 0·25 per 1,000 in 1896. Twenty-six of the 31 districts were free from the disease, and in the remainder it was severe only in the famine-stricken district of Hissar, where 538 deaths occurred, being equal to a death-rate of 0·69 per 1,000. The entire province was quite free from cholera until June, in which month 11 deaths were recorded, rising in July to 160, and falling each subsequent month, until in November and December the province was again free from the disease.

The severe epidemic of small-pox which visited the province in 1896 and caused a mortality of 45,084 and a death-rate of 2·19, which was the highest reached in any year since 1879, diminished during the year under notice to 16,077 or 0·78. All the districts were affected, but the disease was most fatal in Bannu, with a death-rate of 3·82 per 1,000, followed by Hazara with a ratio of 2·38 per 1,000, and by five other districts whose death-rates were above 1 per 1,000. Of the total 16,077 deaths from this disease 31 per cent. were infants under one year of age, and 53 per cent. were children between the ages of 1 and 12.

The deaths ascribed to fevers numbered 422,826, giving a death-rate of 20·57 per 1,000, against 393,535 or 19·15 in 1896. The provincial rate was exceeded by 19 out of the total 31 districts, the highest being Dera Ismail Khan 40·49, Muzaffargarh 37·99, Hissar 34·23, Bannu 32·71, Dera Ghazi Khan 31·15, and Jhang 26·56. Malarial fever was the cause of the high mortality in these districts.

From dysentery and diarrhœa 15,851 deaths were registered, being equal to 0·77 per 1,000 of population, against 13,886 or 0·68 in 1896. Eight districts recorded a higher mortality under this head than the provincial rate, the highest being Hissar 2·02, Simla 2·01, Gurgaon 1·89, Delhi 1·38, and Kangra 1·11.

Plague appeared in the province in an epidemic form during the year. The disease first appeared in Khatkar Kalan, a village in the Jullundur district. By the end of the year it had attacked four other villages, and proved fatal in 175 cases out of a total of 302.

Central Provinces.

The year 1897 in the Central Provinces was exceptionally unhealthy. The famine which began in November of the previous year reached its climax in 1897, and during

the first two quarters of the year the numbers on relief rose till they reached 7 per cent. of the population. In the last quarter all immediate traces of the famine had disappeared, and by the end of the year all relief operations had been closed. The vital statistics of the year were the most unfavourable ever recorded. The registered births were fewer by 46,454 than in 1896, the number having declined from 301,427 or 31·72 per 1,000 to 254,973 or 26·83, the lowest rate recorded since 1881, and the lowest of all provinces in India except Coorg. In 14 of the 20 districts fewer births were registered than in the previous year. "There can be no doubt," the Chief Commissioner again remarks, "that the birth-rate affords a certain indication of the extent to which "distress is affecting the working classes. It is only where the numbers in receipt "of relief never exceeded 0·35 per cent. of the population that the birth-rate of the year "exceeds the death-rate."

The deaths of the year numbered 658,822 or 69·34 per 1,000, against 468,469 or 49·31 in 1896. This abnormal mortality was in great part due to widespread and destructive epidemics of cholera and fever. The number of deaths exceeded the decennial mean by 372,832 and the death-rate was more than double or 39·38 above the mean. The provincial death-rate was exceeded in nine districts, viz., Mandla (98·36), Bilaspur (95·54), Saugor (87·25), Balaghat (86·95), Raipur (78·55), Narsinghpur (78·48), Betul (73·54), Jubbulpore (72·15), and Seoni (71·57).

Cholera was again exceptionally prevalent, and was fatal in 57,131 cases as compared with 52,985 in 1896, the death-rates being 6·01 and 5·58 respectively. The excessive death-rate of the year from cholera was exceeded only in 1869. The disease prevailed in every district of the province, but it was most severe in Mandla (11·62), Raipur (10·04), Bilaspur (9·87), Narsinghpur (7·50), Damoh (7·02), and the provincial mean was exceeded in four other districts. Only in the district of Burhanpur was the mortality less than 1 per 1,000. May and June were again the most fatal months, when 15,642 and 21,125 deaths respectively were recorded.

Small-pox was less prevalent than in the previous year, and the deaths fell from 7,747 or 0·82 per 1,000 in 1896 to 3,641 or 0·38. The disease was widespread and affected every district without exception. In proportion to population the districts of Bilaspur, Sambalpur, and Raipur suffered most, their ratios of mortality being 0·73, 0·89, and 0·92 respectively. In no other district was the mortality above 0·50 per 1,000. The disease prevailed as usual with the greatest intensity in the hot months and declined in the monsoon season. Of the total small-pox deaths about one-fourth (888) occurred among infants, and 1,428 were children under 10 years of age.

Nearly 60 per cent. of the total deaths were ascribed to fevers, and the number registered during the year was 389,335 or 40·98 per 1,000 of population, against 280,760 or 29·55 in 1896. "The term fevers," the Sanitary Commissioner (Dr. Hutcheson) writes, "is "very indefinite as regards the cause of death; and much of the general mortality "from a great variety of causes is included under this head. In fact, owing to "the ignorance of the reporting agency, the term is frequently used to indicate the "cause of death generally, and may be, and is, applied to diseases with no relation to, or "connected with, specific or malarial fevers." The provincial death-rate from fever was exceeded by nine districts, with ratios of mortality ranging from 60·77 to 41·26. The average town death-rate under this head was 29·16, against 22·65 in the previous year.

From dysentery and diarrhœa the registered mortality rose from 29,882 or 3·14 per 1,000 of population in 1896 to 81,092 or 8·53, a mortality "clearly indicating the severity and "extent of the late famine, and the distress and suffering which affected a large proportion "of the population." The highest death-rate under this head was recorded by the Murwara district (24·14), followed by Mandla (23·12), Jubbulpore (17·99), Narsinghpur (14·03), Damoh (12·54), Hoshangabad (11·99), Seoni (11·54), Balaghat (10·70), and Saugor (8·75). The mortality from these causes was excessive in every month of the year and greatest in August and September.

Burma.

Births and deaths continued to be recorded throughout Lower Burma and in four municipal towns of Upper Burma. It is proposed to introduce the system of registering deaths into the more populous and civilised areas of Upper Burma from the beginning of 1899. In the area under registration in Lower Burma 143,659 births were recorded in 1897, giving a birth-rate of 31·82 per 1,000 of population, as compared with 145,688 or 32·27 in 1896. That there is still much room for improvement is shown in the variations in the district rates, which ranged from 40·97 in Sandoway and 40·43 in Pegu

to 17·61 in Rangoon. The number of deaths registered was 118,570, giving a death-rate of 26·26 per 1,000 of population, against 106,687 or 23·63 in 1896. By districts the ratios ranged from 14·44 in Mergui to 38·33 in Rangoon. The death-rate was the highest on record, and was attributed to better registration. With a view to further improvement amended rules have been issued for the collection and record of statistics of births and deaths, and, in the opinion of the Lieutenant-Governor, "the system of registra-" tion now appears to be theoretically perfect, so far as it can be, having regard to the nature " of the agency employed."

Of the chief causes of mortality, cholera was much more active and widespread than in 1896, and the number of deaths rose from 2,959 or 0·66 per 1,000 to 8,538 or 1·89. All the districts were visited by the disease, except Sandoway, Tavoy, and Mergui, but the epidemic was most severe in the Irrawaddy and Pegu divisions, which were responsible for 3,886 and 2,586 deaths respectively. Cholera was present throughout the year, the months of greatest mortality being March, April, May, and July, when it took a downward course and reached its lowest ebb for the year in December. It is reported that nowhere in Upper Burma did the disease appear in an epidemic form during the year.

Deaths from small-pox were slightly more numerous than in 1896, viz., 1,950 or 0·43 per 1,000, against 1,669 or 0·37. Of these, 375 or 19 per cent. were infants and 890 or 46 per cent. were children over one and under 12 years of age. Pegu (1·60) and Toungoo (1·36) were the only instances in which the small-pox death-rate reached 1 per 1,000. In two out of the three districts of the Arakan division no deaths were recorded from this disease, while in the other (Akyab) there was only one death; the district of Tavoy was also free, and Mergui had only one death. Unprotected cooly immigrants from India are reported to be a prolific field for the propagation of this disease, and proposals for remedying the evil were under consideration; but in the majority of cases inoculation is said to be responsible for outbreaks of the disease.

Deaths ascribed to fever rose from 51,521 or 11·41 per 1,000 in 1896 to 51,752 or 11·46, a higher number than had been recorded in any previous year. By districts the death-rate was highest in Sandoway (19·10), Toungoo (17·08), and Akyab (16·35). In six other districts the provincial rate was exceeded, and in the remainder the rates ranged from 10·39 to 7·74. The town death-rate from fever was 7·53 and the rural rate 12·05, as compared with 8·39 and 11·87 in 1896.

The deaths registered under dysentery and diarrhœa during the year aggregated 8,793, giving a death-rate of 1·95 per 1,000, against 7,777 or 1·72 in 1896. The highest mortality under this head was recorded by Toungoo 3·61, followed by Bassein 3·35, Rangoon 3·28, and Thaton 3·14; in the remaining 14 districts the death-rates ranged from 2·42 to 0·36.

Registration of vital statistics in Assam is still very defective. The total number of births registered during the year 1897 was 163,617, giving a ratio of 32·59 per 1,000 population, as compared with 169,172 or 33·69 in 1896. The highest birth-rate was again recorded by Goalpara district, viz., 45·52, followed by Sylhet and Lakhimpur with a rate of 35·17 each, and Cachar 33·04, these being the only four instances in which the provincial rate was exceeded, as the rates of the remaining districts ranged from 29·85 in Sibsagar to 19·77 in Nowgong. **Assam.**

The year was exceptionally unhealthy and the deaths registered during 1897 aggregated 254,093, exceeding the births by 90,476 and the mortality of 1896 by 71,676. The death-rate was 50·61 per 1,000 of population, as compared with 36·33 in 1896. In the Surma Valley, comprising the districts of Cachar and Sylhet, the average mortality rose from 35·43 in 1896 to 54·21, both districts contributing to the increase. In the Brahmaputra Valley the average death-rate was 46·97, as compared with 37·39 in the previous year. Of the six districts in this division Golpara recorded the highest mortality of 50·53 per 1,000, followed by Nowgong with 50·40, the ratios of the remaining four districts ranging from 47·67 to 41·72.

The high mortality of the year was greatly due to a severe outbreak of cholera in the Brahmaputra Valley where the deaths from the disease rose from 7,586 in 1896 to 23,620. The total number of deaths from cholera in the province during 1897 was 33,240 or 6·62 per 1,000, against 17,042 or 3·39 in 1896. The disease prevailed throughout the year and visited every district. Some of the districts recorded a very high cholera death-rate, notably Kamrup and Goalpara in the Brahmaputra Valley, their respective rates, being 17·48 and 10·35, against 1·49 and 3·44 in 1896. In the two Surma Valley districts (Cachar and Sylhet) the rates were respectively 6·31 and 3·36. The average death-rate from cholera in the towns was 15·44 per 1,000, against 6·43 in the country. In some of

the towns the cholera death-rates were excessively high, especially in the Sadr towns of Tezpur and Dhubri, which registered 62·08 and 58·86 respectively.

Cholera was again very prevalent among tea-garden coolies who travelled up the Brahmaputra Valley in steamers. Among them there were 474 deaths; and 934 deaths occurred among the coolies at the depots, after landing.

The mortality from small-pox was almost the same as in the previous year, the deaths numbering 5,420 or 1·08 per 1,000, against 5,444 or 1·09. The highest rates were returned by Sibsagar (5·10), Lakhimpur (2·27), and Kamrup (2·06). In the Sadr and sub-divisional towns, in most of which vaccination is compulsory, the small-pox death-rate fell from 1·27 to 0·50 per 1,000. Of the total small-pox deaths, nearly 20 per cent. occurred among infants, and nearly 53 per cent. among children between the ages of 1 and 12 years.

About 57 per cent. of the year's mortality was ascribed to fevers, including kala-azar. The number of deaths registered from them was 144,307, representing 28·74 per 1,000 of the population, against 101,347 or 20·18 in 1896. The increase occurred chiefly in the Surma Valley where in Sylhet district the death-rate rose from 15·71 in 1896 to 30·89, and in Cachar from 12·76 to 35·30. But the highest fever death-rate was again recorded by Nowgong, viz., 41·77. The provincial fever death-rate was also exceeded by Goalpara (34·72) and Darrang (30·30). Of the 18,612 kala-azar deaths, 12,012 occurred in the Nowgong district, an increase of 1,424 on the number of the previous year. Owing to the high mortality from kala-azar in Nowgong, and its continued prevalence in other places, a specialist (Surgeon-Captain Rogers) was appointed in 1896 to investigate and report on the disease. The result of his enquiry shows that the disease is not, as had been supposed, identical with anchylostomiasis, and that its symptoms are in no way different from those of a very intense form of malarial fever, and that it is communicable. He recommends segregation and quarantine and the abandonment of infected sites. Steps have been taken to induce the people of the affected tracts to adopt the remedial measures recommended by Dr. Rogers for checking the spread of the epidemic, but hitherto without much success.

Under dysentery and diarrhœa 23,136 deaths were registered, yielding a ratio of 4·61 per 1,000 of population, as compared with 16,004 or 3·19 in 1895. As usual, these diseases were most prevalent in Lakhimpur district, its death-rate under this head being 11·66. The next highest rates were 8·97 in Sibsagar district, 8·24 in the Khasi and Jaintia Hills, and 7·34 in Cachar district. The unusually high death-rate from these diseases in the Khasi and Jaintia Hills is stated to have been due to the effects of exposure after the earthquake.

Madras.

The number of births registered in Madras Presidency during the year was 935,845 or 28·7 per 1,000, against 979,981 or 29·9 in 1896. The decrease extended to 15 of the 22 districts, and was attributed by the Sanitary Commissioner, Dr. King, to the influence of famine in certain areas, and deferred marriages owing to the unfavourable state of agricultural prospects. Excluding Madras town, which recorded a birth-rate of 41·6, Chingleput again registered the highest ratio of 37·1, and in six other districts the rate was above 30 per 1,000, while in Ganjam and Malabar the rates were only 23·9 and 20·8 respectively. Among the 59 municipalities, 8 recorded birth-rates over 40 per 1,000, 14 over 35, and 20 over 30 per 1,000. The mortality in 1897 exceeded that of the previous year by 151,738, the deaths having risen from 675,787 or 20·6 per 1,000 to 827,525 or 25·4. By districts the highest death-rate was recorded in Ganjam, viz., 50·1, followed by Madras 35·4, which was less by 2·4 per 1,000 than that recorded in the previous year. In the other districts the mortality ratios ranged from 31·6 per 1,000 in Vizagapatam to 19·3 in Salem. The average death-rate of the towns was 31·9 per 1,000, and that of rural areas 24·8.

Of the chief diseases, cholera was considerably more fatal than in 1896, the number of deaths having risen from 47,847 or 1·5 per 1,000 to 143,445 or 4·4. All the districts were affected, but the disease was most severe in Ganjam and Malabar, which recorded cholera death-rates of 12·5 and 10·4 respectively. The Sanitary Commissioner states that in both these districts the predisposition of the population was increased by conditions of scarcity, and that the medical officers maintain that diarrhœa of a character simulating cholera was due to the eating of unripe food by the people. The next highest death-rate from cholera was 7·5 per 1,000 in Tanjore, followed by 6·0 in Madura, and 5·9 in Anantapur; in the remaining districts the rates varied from 4·7 in Kurnool to 0·3 in Madras. The average death-rate in municipal and other towns from the disease was 5·0 per 1,000, against 2·3 in 1896, and that in rural tracts 4·3, against 1·4.

Small-pox deaths were reported from all the districts, and the total in the whole Presidency aggregated 21,678 or 0·7 per 1,000, against 9,410 or 0·3 in 1896. Of the districts, the disease was very severe in Ganjam, which returned 14,515 or about two-thirds of the total. The disease was also severely felt in Anantapur and North Arcot, while in Malabar, where it was most destructive in previous years, there were only 43 deaths. Of the total 21,678 small-pox deaths 4,573 or over 21 per cent. occurred amongst children under 1 year of age, and 10,120 or nearly 47 per cent. among those between 1 and 12 years of age.

From fevers the registered deaths rose from 260,769 or 7·97 per thousand to 292,292 or 9·0. The excess mortality from fevers occurred in the last seven months of the year, the deaths up to June having been fewer than in the previous year. "The comparative "freedom in the early part of the year," Dr. King states, "must be ascribed to the "diminished soil moisture proving inimical to the propagation of the malarial germ, in "consequence of failure of the north-east monsoon of the previous year; this was followed, "on access of moisture with the south-west monsoon, in the presence of a population "rendered susceptible to malaria owing to diminished food supply, by a mortality greater "than normal under this head." The highest district rates were recorded in Vizagapatam (23·8), Ganjam (19·2), Kurnool (18·1), and the Nilgiris (17·0); four other districts had ratios of over 10 per 1,000, and ten over 5 per 1,000. Nine of the 59 municipal towns returned fever death-rates exceeding 10 per 1,000, the highest being 21·7 in Kurnool, followed by 14·2 in Bellary and 13·9 in Vaniyambadi.

The number of deaths registered under dysentery and diarrhœa in the Presidency was 38,716 or 1·2 per 1,000, an increase of 3,914 on the mortality of 1896. The excess was contributed by 13 of the 22 districts, of which seven were formally recognised as suffering from famine, whilst in the others there was considerable distress. Of the districts, Madras came first with a death-rate from this cause of 4·5, against 5·3 in the previous year, followed by Malabar with 3·3, and South Canara with 3·2; three other districts had ratios of 2 per 1,000. Of the towns, Bimlipatam recorded the high death-rate of 8·5 per 1,000, followed by Cochin 7·8, and Coonoor 7·2. Owing to the continued presence of these diseases in Coonoor, Dr. King urged on the municipal authorities the adoption of a sound water supply scheme, "if it did not wish the fame of Coonoor as a sanitarium "to pass away from it for ever."

Bombay.

The year 1897 in the Bombay Presidency was again an unhealthy one. "The plague "and famine," the Sanitary Commissioner (Surgeon Lieutenant-Colonel Clarkson) writes, "which had visited the Presidency in the latter half of the year 1896, continued on in "1897, and great suffering and a high death-rate has resulted. The plague continued "throughout the year, but owing to the timely rainfall, especially in September, the "cultivators were encouraged to return to till their fields, and the famine works closed "except in three places."

In the Presidency, including Sind, 629,693 births were registered during the year, giving a birth-rate of 33·46 per 1,000 of population, as compared with 691,247 or 36·76 in 1896. Of the 24 collectorates and districts only three recorded higher rates than in the previous year, the remainder showing a decrease, especially Bombay City, where the birth-rate, usually low, was rendered still lower by the exodus of the people on account of plague. More children were registered as still-born in Bombay City than in any other district, and the percentage of still-born to born alive was 14·88. The causes are the same as those mentioned in previous reports, viz., overcrowding on unhealthy areas and living in badly ventilated rooms, to which may be added the kind of work women have to labour at.

The total number of deaths registered in the Presidency rose from 596,742 in 1896 to 749,916, and the rate per 1,000 of population from 31·69 to 39·84, which was made up of district ratios ranging from 58·88 in Bombay City to 15·92 in Hyderabad. The increase of 153,274 deaths was spread over all the districts except six, and was common to all the specified causes of death. The excess was most marked in Bombay City, Poona, Nasik, and Satara, in all of which plague was virulently epidemic. The month of greatest mortality was August, when 82,743 deaths were registered, after which the mortality gradually lessened.

Of the chief diseases, cholera was more prevalent than usual, owing to the famine, and caused 57,109 deaths, giving a ratio of 3·03 per 1,000, as compared with 35,404 or 1·88 in 1896. The province of Sind was practically free from cholera, only one death being reported (from Karachi district) during the year. All the other districts were affected.

The epidemic was specially severe in Satara, Poona, Belgaum, Bijapur, Sholapur, Kolaba, Ahmednagar, and Nasik districts, the ratios of which ranged from 9·03 to 4·04 per 1,000. Many of the towns recorded high rates, the highest being 26·63 in Nasik and 12·32 in Pandharpur in Sholapur district. Deaths occurred in every month of the year, the months of greatest prevalence being May to August; the maximum of 14,749 was reached in August.

Small-pox deaths fell from 6,443 or 0·34 per 1,000 in 1896 to 3,835 or 0·20. Every district was affected, but only in two did the death-rate reach 1 per 1,000, the highest rates recorded being 1·13 in Broach and 1·01 in Thar and Parkar. According to age, 29·46 per cent. of the small-pox deaths occurred among infants under one year of age, and 46·39 per cent. among children between the ages of 1 and 12.

The number of deaths registered in the Bombay Presidency as due to fevers was 452,596 or 24·05 per 1,000 of population, against 412,229 or 21·90 in 1896. The average rate was exceeded in 11 districts, among the highest being 33·35 in Bombay City, 32·22 in Poona, 32·15 in Satara, and 31·93 in Nasik. The increase of 40,367 was shared in by 12 out of the 24 collectorates. As regards the monthly distribution of deaths due to fever, the Sanitary Commissioner states: "In spite of the plague, the fever mortality which was "noted as low in the last three months of the year 1896, continued below the figures of the "corresponding months of the previous year up to the end of May 1897, but exceeded "the 10-year mean. In June the lowest fever mortality for the year (31,018) is as usual "reported, though it is higher than that of the corresponding month of the previous year "(29,255), and the corresponding decennial period (25,737). After June a rise takes "place, and the maximum mortality is reported in August (44,547), and continues high "till the end of the year."

The number of deaths ascribed to dysentery and diarrhœa aggregated 85,966 or 4·57 per 1,000 of population, against 36,046 or 1·92 in 1896. In all but two of the 24 districts the mortality was higher than in the previous year, the greatest increase being in Sholapur, where the death-rate under this head rose from 2·36 to 12·22. Poona came next with 9·70 against 2·69 in 1896, followed by Nasik with 9·32 against 4·73, and in 7 other districts the rates were higher than the average for the Presidency. "There is no doubt," the Sanitary Commissioner writes, "that the large rise in mortality from dysentery and "diarrhœa is due to famine. In areas where the famine most prevailed the mortality "is seen to be the highest, and those areas upon the fringe of the famine the death-rate "is also high."

From plague 46,944 deaths were reported during the year, giving a ratio of nearly 2·5 per 1,000 of population. The outbreak commenced in September of the previous year, at the end of which 2,086 deaths had been reported, being equal to a ratio of 0·12 per 1,000. Up to the end of 1896 ten of the 24 districts had remained free of the disease, but in spite of precautions to check its progress, plague had extended to all but two (Kanara and Panch Mahals) of the districts by the close of 1897, though some were but slightly affected. Of the 46,944 deaths, Bombay City contributed 10,237, Satara district 10,031, and Poona district 8,871. An interesting account of the history and progress of the plague and of the measures taken to suppress it, will be found in the Abstract of the Report of the Sanitary Commissioner with the Government of India, at pages 107–136.

Berar.

The public health of Berar in 1897 was not satisfactory, owing chiefly to the effects of the famine. The total number of births registered in the course of the year was 113,364 or 39·7 per 1,000 of population, showing an increase of 4,351 or 1·4 on the previous year. But although there was a rise in the provincial birth-rate as compared with 1896, the increase was confined to the first six months of the year, "before the effects of the "famine had had time to diminish the fecundity of the population," as towards the end of the year the birth-rate fell considerably. In the six districts of the province the birth-rates ranged from 40·4 in Akola to 37·0 in Basim.

The deaths rose from 124,787 or 43·8 per 1,000 in 1896 to 150,222 or 52·6, a rate which has only been exceeded once since the commencement of registration in 1868, and then only in the famine year of 1878, when the excessive rate of 81·5 was recorded. The increase occurred chiefly under dysentery and diarrhœa, which accounted for 11,827 of the excess mortality. Amraoti district recorded the highest death-rate, 61·1; Akola came next with 55·5, Ellichpur 54·9, Buldana 54·2, Basim 43·5, and Wun 42·1, which was the only case of a decrease on the previous year's death-rate (50·5). The high death-rate of Amraoti district as compared with others was attributed to its close proximity to the Central Provinces, from which the starving poor flooded the

district seeking for work and food. "Numbers of these people," it is reported, "died "from the effects of chronic starvation from which they suffered before reaching Berar, "with the result of unduly raising the death-rate." In municipalities, the average death-rate rose from 43·4 in 1896 to 54·5, which was made up of ratios ranging from 91·9 to 21·8.

Cholera, though again epidemic during the year, was not so prevalent as in 1896, as the deaths fell from 12,264 or 4·3 per 1,000 of population to 10,122 or 3·5. The disease affected every district, and prevailed throughout each month of the year. According to districts, the highest death-rate was recorded in Akola, where there were 3,244 cholera deaths, equal to a ratio of 5·6 per 1,000, against 1,424 or 2·5 in 1896. Amraoti came next with a cholera death-rate of 4·4. Of the 38 towns only four escaped the disease, and in 24 of these the death-rates exceeded the average for the province. Out of a total of 5,658 villages cholera prevailed in 596 or 10·6 per cent., as against 704 in 1896.

From small-pox, 617 deaths were registered, giving a ratio of 0·2 per 1,000 of population, as compared with 810 or 0·3 in 1896. More than half the deaths (318) were registered in Akola district, and the fewest (11) in Ellichpur district. Although the disease was present in several towns, it attained serious proportions in very few. Seventy per cent. of the deaths occurred amongst children under 12 years of age, 191 or 31 per cent. being infants under one year.

Under fevers, a mortality of 65,611 or 23·0 per 1,000 was registered, against 61,931 or 21·8 in 1896. By districts the death-rates from fever varied between 30·6 in Wun and 18·0 in Basim. Notwithstanding the general increase in the provincial mortality from fevers, there was a considerable falling off in the admissions under this head in the medical institutions which is explained by the fact that a large proportion of the deaths occurred amongst the famine-stricken poor, "with whom the question of medical relief "was secondary to that of food wherewith to sustain life, and who did not resort to the "dispensaries for medical treatment."

The number of deaths attributed to dysentery and diarrhœa was 29,549 or 10·3 per 1,000, against 17,722 or 6·2 in 1896. Ellichpur district, as usual, recorded the highest mortality under this head, viz., 16·4, against 10·3 in the previous year. Akola followed with 13·0, which was also higher than the ratio (8·0) of the preceding year. The other district rates ranged from 12·7 in Amraoti to 2·7 in Wun.

IV.—JAILS.

Sickness and mortality in 1897.

The general state of the public health and the meteorological conditions of the year 1897 were unfavourable to the jail population of India. Scarcity and famine, consequent on the drought of the previous year, had so affected the public health that a great proportion of prisoners admitted to jail were in a weak and emaciated condition. Scarcity and high prices led to an abnormal influx of prisoners, and consequently there was much overcrowding in the jails. The daily average sick per 1,000 of average strength fell from 39·54 in 1896 to 39·31, while the ratio of admissions into hospital rose from 939 to 975, and the death-rate from 27·79 to 39·64. There was an increased mortality in all the provinces except Assam, where the jail death-rate fell from 50·86 in 1896 to 48·69. From cholera there were 436 deaths, as compared with 142 in 1896. In the jails of the Punjab, Berar, and Coorg there were no deaths from this disease.

The following statement shows the sickness and mortality among all classes of prisoners in the jails and subsidiary jails of the several provinces for 1897, as compared with the previous year :—

Provinces.	1897.			1896.		
	Ratio per 1,000 of Average Strength.			Ratio per 1,000 of Average Strength.		
	Admissions.	Daily Sick.	Deaths.	Admissions.	Daily Sick.	Deaths.
Bengal	1,083	26	34·4	1,154	39	28·78
North Western Provinces and Oudh.	1,019	50	35·47	897	51	28·83
Punjab	1,340	31	16·3	1,237	31	15·68
Burma	596	29	24·04	759	35	18·19
Central Provinces	1,233	65	134·98	1,108	40	72·11
Assam	1,255	51	48·69	1,128	51	50·86
Coorg	479	11	25·21	1,042	31	20·85
Madras	672	30	47·45	583	25	19·51

Berar	550	16	34·77	594	18	25·13
India	975	39	39·64	939	40	27·79

Bengal.

The statistics of the Bengal jails for 1897 show that there was less sickness among the jail population of the province, with an increased mortality. The admissions into hospital were in the ratio of 1,083 per 1,000 of average strength, against 1,154 in 1896, the average daily sick-rate was 26 or 13 per 1,000 less, while the death-rate rose from 28·8 to 34·4. Among all classes of prisoners there were 684 deaths, and of these 591 were convicts. Many of the jails were overcrowded during the year, and on the whole the health of the prisoners when admitted was bad, especially those received from famine stricken districts. The diseases which contributed largely to the convict death-rate (34·0) were dysentery and diarrhœa 222 deaths, respiratory diseases 70, pneumonia 67, malarial fever 54, and cholera 46. In the previous year there were 60 deaths from cholera amongst the convicts. The jails principally affected by cholera were those of Daltonganj, Hazaribagh, and Ranchi in the Chota Nagpur division, where the deaths numbered 12, 11, and 5 respectively. Of the convicts who died in jail 23 per cent. were admitted in good health, nearly 32 per cent. in indifferent health, and 45 per cent. in bad health. Out of 47 jails the average death-rate among convicts was exceeded in 23, the highest being 315·1 in Daltonganj against 168·0 in the previous year, Ranchi 115·3 against 40·8, Purulia 94·6 against 25·2, and Barisal 91·5 against 50·7. In five other jails the mortality ranged from 84·6 to 60·4 per 1,000, and in four more over 50 per 1,000. In three jails there were no deaths. The high mortality of the Daltonganj jail was due to the bad state of health of the prisoners admitted, and to cholera, which was the cause of more than half the mortality. The high death-rates at Purulia and Ranchi were due to cholera and dysentery and diarrhœa, diseases usually associated with privation. In

many jails where sanitary improvements were being carried out work was hindered on account of diversion of funds to meet the expense of repairs rendered necessary by the earthquake which occurred on the 12th June 1897.

North-Western Provinces and Oudh.

The effect of scarcity and famine again considerably augmented the criminal population in the North-Western Provinces and Oudh, and during 1897 all the jails except ten were overcrowded. The overcrowding was, however, confined to male convicts, of whom, it is stated, "there were in confinement an average of 4,441 in excess of the number for whom "accommodation is provided." Notwithstanding, the vital statistics do not disclose any marked evil effects therefrom, which "speaks well for the administration and sanitary "condition of the jails."

The admissions into hospital rose from 897 per 1,000 of average strength in 1896 to 1,019, the daily average sick-rate fell from 51 to 50 per 1,000, while the death-rate rose from 28·83 to 35·47. Of the 57 jails in the province, four recorded a death-rate of over 100 per 1,000 and 13 of over 50 per 1,000, the highest being 166·6 in Orai district jail, the result of 37 deaths, 13 of which were due to cholera, 11 to dysentery, and 5 to pneumonia. Several of the jails recorded a very low death-rate, chief among them being Lucknow Central Prison, where there were only 18 deaths, equal to 10·6 per 1,000 on an average strength of 1,696 convicts, a remarkable record since the death-rate of the surrounding district was as high as 51·16 per 1,000. Of the causes of death, cholera in an epidemic form was again absent, only 46 deaths from the disease having been recorded in 1897 in all the jails, against 14 in the previous year. Dysentery was accountable for 307 deaths, being about 25 per cent. of the total number of 1,286. The mortality from diarrhœa was also much greater, 106 deaths having occurred, against 72 in the previous year. Of the total deaths, 1,178 were of convicts, the death-rate being 35·2. According to length of residence in jail, the highest mortality occurred among convicts of over seven years standing, viz., 46·0, followed by those during the first six months of imprisonment, viz., 44·4.

Punjab.

The vital statistics of the Punjab jails are not quite so favourable as those of the previous year, they are nevertheless very satisfactory, being with this exception better than in any year except 1868, when the death-rate was only 12·9. The admissions to hospital per 1,000 of average strength rose from 1,237 to 1,340, the daily sick-rate was the same in both years, 31 per 1,000, but there was a slight increase in the death-rate, from 15·68 to 16·33, which is about half the mortality rate of the province. The only excessive death-rate was returned by the small jail at Bannu, viz., 70·71, the result of 7 deaths. In three jails there were no deaths, and in 10 the mortality was below 12 per 1,000. In several other jails the death-rates were below the provincial jail average. Of the total 208 deaths, all but 14 were of convicts, giving a death-rate of 16·66. The mortality from dysentery and diarrhœa and from respiratory diseases, the chief causes of death, was much higher than in 1896; while the admissions from malarial fevers rose 61·42 per cent., and the deaths from the same cause by 41·67 per cent. "Diseases of this class," the Inspector-General writes, "are the chief direct cause of the sickness, and a great indirect cause of the "mortality among the jail population, so that the discovery of some reliable means of "preventing them would be a solution of the health question as it affects prisoners." There was no case of cholera in any jail. Of the total deaths no less than 50 per cent. occurred among prisoners who had been less than six months in jail, "a fact plainly "indicating the necessity for giving special consideration to the convict on admission "to jail, in respect to all matters affecting his health."

Burma.

The Burma jail statistics show that the admissions into hospital and constantly sick during 1897 were much fewer than in the previous year, the ratios per 1,000 of average strength having declined from 759 and 35 respectively to 596 and 29. The death-rate, however (24·04), was the highest since 1894, and exceeded that of 1896 by nearly 6 per 1,000. The increase in mortality was almost entirely due to the greater prevalence of cholera, for excluding the deaths from this disease the death-rate was 18·91 as compared with 17·63 in 1896. The Inspector General observes "that a distinctly injurious influence "on the jail sick and death returns is produced by the constant deportation of a large "proportion of the healthiest prisoners, and by the return from other provinces of such "Burman prisoners as there lose their health." Of the 323 deaths which occurred during the year, 315 were of convicts, the death-rate being 24·11 against 17·75 in 1896. Cholera was responsible for 69 deaths, distributed over 11 jails, but the numbers of fatal cases were less than five, except in the Moulmein (37 deaths), Myingyan (10), and Minbu (8) jails. The disease appeared in the town of Moulmein on the 8th February, but did not affect the

jail till the 17th March, and between that date and the 8th April the whole 37 deaths occurred. Among other diseases, dysentery contributed 49 deaths, diarrhœa 23, tubercle of the lungs, &c., 39, and malarial fevers 11. The jails of the province continued to enjoy complete immunity from small-pox. Several of the jails recorded a very high death-rate, notably Bhamo (136·99 per 1,000), Kyaukpyu (109·65), Pagan (90·91), Pakokku (84·75), Moulmein (81·74), Minbu (69·57), and Katha (64·10), but these jails are small, except Moulmein and Kyaukpyu, and a few deaths give a high rate. It is reported that all but four of the 31 jails in the province were overcrowded at one time or other during the year.

Central Provinces. The vital statistics of the jails of the Central Provinces for 1897 are again extremely unsatisfactory. The admissions into hospital per 1,000 of average strength rose from 1,108 in 1896 to 1,233, the daily average sick-rate from 40 to 65 per 1,000, and the death-rate from 72·11 to 134·98. These unfavourable results were almost entirely due to the condition of the new admissions, many of them being in a state of extreme emaciation owing to privation through the famine which prevailed in almost every district of the province. Out of the total number of 999 deaths, more than half were caused by dysentery and diarrhœa, chiefly by a highly fatal and malignant form of the former disease. Only one (Damoh) of the nineteen jails recorded a lower mortality as compared with the previous year, and only in three could it be said that the mortality was not excessive. Those of Balaghat, Bilaspur, Mandla, Damoh, Saugor, Seoni, Narsinghpur, Betul, Sambalpur, Chhindwara, and Hoshangabad furnished the highest figures, their ratios ranging from 590·7 to 120·4 per 1,000. Among other diseases, pneumonia and other respiratory diseases caused 69 deaths, fevers 17, and cholera 25. In the previous year there were 15 fatal cases of cholera. All but 53 of the 999 deaths occurred amongst convicts, the death-rate being 138·34, against 73·90 in 1896. Every prison in the province is reported to have been overcrowded, and in some instances the overcrowding was excessive.

Assam. Among the prison population of Assam the rate of admissions to hospital rose from 1,128 per 1,000 in 1896 to 1,255 in 1897, the daily sick-rate remained the same (51), while the death-rate fell from 50·86 to 48·69. The mortality would have been much less but for the earthquake which killed 10 prisoners in the Sylhet jail, and the murder of a prisoner by a fellow convict at Dibrugarh. Excluding these 11 deaths, the death-rate for the whole of the province is reduced to 41·3 per 1,000—"a creditable result," the Government of India observe, "in view of the facts that scarcity was prevalent, that the year was "a particularly unhealthy one, and that many of the prisoners were exposed for a time to "unusual hardships consequent on the demolition of buildings by the earthquake." The improvement in the general health is attributed to a more suitable dietary, better clothing, and to greater strictness in respect of extra-mural labour, for the regulation of which rules have been sanctioned by the Chief Commissioner. In only three of the 22 jails was the average strength above 100, viz., Sylhet, Tezpur, and Gauhati, and these three accounted for 45 out of the total 73 deaths, and their death-rates per 1,000 were respectively 44·03, 48·95, and 67·70. In most of the other jails the average strength was less than 50. As in the previous year many prisoners were admitted into jail in a moribund condition; of the 14 prisoners who died (excluding the 10 caused by the earthquake) from natural causes in Sylhet only 2 were admitted in good health, only 4 out of 11 in Tezpur, and only 2 out of 10 in Gauhati. All but seven of the 73 deaths occurred amongst convicts, being in the ratio of 48·14 per 1,000 against 52·46 in 1896. Cholera was present in six jails and was the cause of death of 11 convicts, as compared with one in the previous year; from dysentery and diarrhœa there were 20 deaths, and from malarial fevers 11.

Madras. In the jails of Madras Presidency the hospital admission rate rose from 583 per 1,000 of average strength in 1896 to 672 in 1897, the daily sick-rate was 30, or 5 per 1,000 more, and the death-rate rose from 19·51 to 47·45, which was the highest since 1879. The emaciated condition of a number of prisoners received from localities affected by famine swelled the sick-rate, and the heavy mortality was mainly due to outbreaks of cholera which occurred in 5 district and 5 central jails. Of the total 490 deaths nearly half (236) were due to cholera, against only two in the previous year. Excluding deaths from this disease the death-rate was equal to 24·6 per 1,000. The Coimbatore and the Rajahmandry central jails suffered most seriously from cholera, the former returning 111 fatal cases out of a total mortality of 146 and the latter 76 out of 125. The highest death-rate was that of Coimbatore jail, 169·13 against 26·15 in 1896, and that of Rajahmandry was 123·08 against 47·09. Apart from cholera, the health of the prisoners at Rajahmandry was not good, owing chiefly to scarcity in the surrounding districts from which prisoners were

sent to the jail. In none of the other jails with a strength of over 200, except Vizagapatam with a death-rate of 58·95, did the mortality reach the Presidency rate ; while in seven jails there were no deaths. Dysentery and diarrhœa and respiratory diseases followed cholera in order of mortality among the prisoners, the death-rate from the former being 8·68 per 1,000, and from the latter 3·14. Of the total 490 deaths convicts contributed 438, representing a ratio of 50·49 per 1,000 of average strength, as compared with 20·33 in 1896.

Bombay.

In spite of plague and famine, there was less sickness among the prison population of the Bombay Presidency during 1897 than in the previous year, but the mortality was higher. The rate of admissions to hospitals per 1,000 of average strength fell from 861 to 807, the daily sick-rate (26) was 6 per 1,000 less, while the death-rate rose from 31·89 to 35·28 per 1,000. Seven out of the 18 jails recorded death-rates above the average, viz., Sind Gang 148·6, Thana jail 118·9, House of Correction 86·3, Nasik jail 66·7, Common Prison 52·5, Shikarpur jail 45·6, and Ratnagiri jail 41·9. All but 38 of the total 331 deaths (including 20 in the lock-ups) occurred among the convicts, their death-rate being 37·8 or 4·4 per 1,000 more than in 1896. The chief causes of mortality were cholera 41 deaths, dysentery and diarrhœa 43, respiratory diseases 67, including 58 from pneumonia, fevers 24, plague 27, and tubercle of the lungs, &c., 24. Of the 41 cholera deaths 37 occurred in the Thana jail and formed more than a third of its mortality. The epidemic broke out in July and lasted 21 days, during which all the 37 deaths occurred. This is the third time within ten years that cholera has appeared in this jail in an epidemic form. In the previous year the outbreak occurred in the same month (July), and lasted 27 days when there were 24 deaths. The surroundings of the jail are reported to be very unfavourable to health, and the drinking water has been repeatedly condemned by the Chemical Analyser to Government. The jail was visited by the Inspector-General and the Sanitary Commissioner in 1896, and as a result of their visits the pipes distributing the water have been renewed and relaid, and arrangements have been made for gradually filling up the moat which partially surrounds the jail. Of the 27 plague deaths, 17 occurred in the House of Correction in Bombay, two in the Common Prison in Bombay, one in Yerrowda jail, and seven in the sub-jail at Surat. Pneumonia, as usual, was very prevalent in the Sind jails, 105 cases, out of a total of 173, having occurred in them, and 40 of the 58 deaths. The Sind Gang was the chief sufferer, with 55 cases and 21 deaths.

Berar.

Although the jails in Berar were overcrowded during 1897 owing to famine and immigration from the Central Provinces, there was less sickness among the prisoners than in the previous year. The rate of admissions into hospital per 1,000 of average strength declined from 594 to 550 ; the daily sick-rate also fell from 18 to 16, while the death-rate rose from 25·13 to 34·77. There was no outbreak of epidemic disease in any of the jails, and the general increase in the mortality was attributed to the enfeebled condition of the prisoners on admission. The deaths numbered 66 against 36 in 1896. The highest mortality was recorded in the Akola jail, where there were 30 deaths giving a death-rate of 46·06, against 14 or 25·72 in 1896, Yeotmal followed with a ratio of 42·93 against 71·92, and next came Basim with 37·21, the result of six deaths. All but four of the 66 deaths occurred amongst convicts, their death-rate being 33·12 per 1,000, as compared with 23·81 in 1896.

V.—VACCINATION.

General results.

During 1896-97 there were 7,144,474 persons successfully vaccinated in the several provinces of India, being a decrease of 138,295 on the number of the previous year. According to age, over $2\frac{3}{4}$ millions (2,804,596) of the total were children under one year of age, and over 3 millions (3,167,955) were children between the ages of one and six years. The proportion of population protected against small-pox by the year's operations ranged from 58·24 in Coorg and 48·08 in Burma to 25·97 in the North-Western Provinces and Oudh. In the vaccination of infants the best results were, as usual, obtained in Berar, the Punjab, and Bombay, where 63·4, 57·5, and 55·5 per cent. respectively of the children born during the year (estimated at 40 per 1,000 of population) were protected against small-pox. In the Central Provinces the percentage was 36·2, and in the remainder it ranged from 34·3 in Burma and 29·2 in the North-Western Provinces and Oudh to 13·1 in Coorg.

Statement showing the total number of persons successfully vaccinated during the year 1897–98 :—

Province.	Population among whom Vaccination was carried on (Census of 1891).	Number of Persons successfully vaccinated.	Ratio of successful Vaccinations per 1,000 of Population.	Number of Children successfully vaccinated.		Percentage of Children born during the Year (calculated at 40 per 1,000 of Population) successfully vaccinated.
				Under One Year of Age.	Between One and Six Years of Age.	
Bengal	70,832,144	2,244,716	30·25	508,615	1,459,490	17·8

TOTAL	226,852,649	7,144,474	31·49	2,804,596	3,167,955	30·9

Bengal.

The total number of vaccinations performed in Bengal during 1897–98 was 2,319,536, of which 2,244,716 were successful, against corresponding figures in 1896–97 of 2,293,655 and 2,213,915. This shows an increase of 25,881 vaccinations in 1897–98, which Dr. Dyson says "is satisfactory, considering that the province was just recovering from the effects " of a severe famine in some places and prolonged scarcity in others." The primary operations numbered 2,243,093, of which 98·04 per cent. were successful. According to age, 508,615 of the successful primary vaccinations were of children under one year of age, and 1,459,490 were between one and six years. For the whole province the successful vaccinations were in the proportion of 30·25 per 1,000 of the population. Estimating the births during the year at 40 per 1,000, the percentage of infants successfully vaccinated was only 17·8, a ratio a trifle higher than that of the previous year, but far below that attained in other provinces except Coorg.

Three methods of vaccination are practised in the province—(1) with lymph taken direct from the calf; (2) with calf lymph prepared with lanoline; (3) with human lymph taken by arm to arm transfer. Compared with the previous year's figures there was an increase of over 30,000 in the number of operations performed direct from the calf. Dr. Dyson anticipates that with the progress of time the prejudices of the Hindus against this method of vaccination will gradually disappear. Steps were taken during the year to ascertain the state of public feeling in regard to extending this system of vaccination, and the results showed that while in some districts there was no objection, in others religious

prejudices stood in the way. Having regard to the state of public feeling in connection with plague measures, the Sanitary Commissioner did not consider it advisable at present to make any attempt to extend the system of calf vaccination in places in which the measure was not readily acceptable to the people.

North-Western Provinces and Oudh.

The steady progress in vaccination which has characterized the North-Western Provinces in previous years was arrested in 1897–98. This was due chiefly to the low birth-rate of the year. There were besides other special difficulties: many of the children in the famine-affected districts were in too reduced a condition to undergo the operation, and the time of the officers of the Vaccination Department was much occupied with plague duties. The total number of persons vaccinated in the North-Western Provinces and Oudh fell from 1,528,478 in 1896–97 to 1,385,005 in 1897–98, and the successfully vaccinated from 1,362,169 to 1,224,603. The proportion of persons protected by vaccination is still very small, the ratio for the year being only 25·97 per 1,000, which is the smallest ratio attained in any province in India, and 2·90 per 1,000 below the ratio of the previous year. Primary vaccinations numbered 1,318,912, of which 93·74 per cent. were successful. Of the 1,224,603 successful primary cases, 551,296 were infants and 482,839 were children over one and under six years of age. Estimating the births at 40 per 1,000 of the population, 29·2 per cent. were successfully vaccinated during the year.

Since the 1st February 1896 the areas of operation have been rearranged in two circles for the purposes of control, each being in charge of a Commissioned Medical Officer, acting as Superintendent of Vaccination and Deputy Sanitary Commissioner. In the first circle, the average ratio of success of its 27 districts equalled 25·65 per 1,000 of the population, against a mean for the five previous years of 28·79. In the second circle, the average ratio of its 22 districts was 26·25, against a five years' mean of 23·47. The Vaccination Act is in force in all the municipalities, but in some places it is not worked as efficiently as it should be. The results show a falling off from 38·55, the ratio of successful vaccinations per 1,000 of population in 1896, to 32·51 in 1897.

Punjab.

There was again a considerable falling off in the number of vaccinations in the Punjab as compared with the preceding year. Altogether 845,491 operations were performed in 1897–98, showing a decrease of 56,922 on the figures of 1896–97. Of the primary cases, 94·40 per cent. were successful. The number of successful cases among children under one year of age fell from 485,204 or 58·5 per cent. of the births, calculated at 40 per 1,000 of population, to 476,723 or 57·5 per cent. The provincial ratio of persons successfully vaccinated per 1,000 of the total population was 35·04, against 36·65 in the previous year. Animal lymph was chiefly used, and during the year nearly 83 per cent. of the primary vaccinations were performed with it. In several districts there was a marked diminution in the primary operations, and this was attributed chiefly to the high mortality among children, and partly to failure of lymph and carelessness of the vaccination staff. It is noticed that in the district of Dera Ismail Khan, out of a total of 28,394 deaths no less than 7,619 were infants under one year of age, and 9,964 among children between one and five years of age.

Burma.

Satisfactory progress was made in vaccination work in the province of Burma during 1897–98. The total number of persons vaccinated was 431,550, as compared with 423,848 in the previous year. The least satisfactory returns were those relating to the town of Rangoon, where there was a decrease of 8,600 on the previous year's operations. It is believed, however, that much vaccination work is performed at Rangoon by private practitioners, the results not being recorded. The percentage of success in primary operations continued to improve. Out of 405,928 primary cases, 94·56 per cent. were successful, against a corresponding ratio of 92·38 in the previous year. The number of infants protected was 111,931, equal to about 34 per cent. of the births, estimated at 40 per 1,000 of the population. The Vaccination Act was extended to Thonze, and is now in force in all the municipalities of the province. Proposals were under consideration for amending the law so as to make the Act applicable to small towns administered by Town Committees.

Central Provinces.

Vaccination work in the Central Provinces was considerably hampered during 1897–98 by the famine, and the decreasing birth-rate has naturally been followed by a fall in the number of primary operations. There were 398,699 persons vaccinated during 1897–98, showing a decrease of 15,110 on the number of the previous year. Primary vaccinations fell from 367,821 to 347,230. The percentage of success in primary cases was 96·67,

against 96·20, and the proportion of the total population protected by vaccination was 28·39 per 1,000, as compared with 30·56 in 1896–97. Of the 18 districts in the province, 12 showed a decrease in primary operations, and six an increase. In the protection of infants there was a falling off of 44,688, the number vaccinated under one year of age during the year having decreased from 232,124 to 187,437. Animal lymph supplied the bulk of the vaccination, and worked very successfully, and there is now very little prejudice against its use in the province. Arm-to-arm vaccination is now practised in very few places. With the lymph obtained from calves, 228,829 children were vaccinated during the year, and of these 209,851 were successful.

ssam. The results of vaccination work in Assam for 1897–98 again compare favourably with those for the previous year. There were 283,914 operations performed by all agencies in the province, which is an increase of 9,218 over the figures of 1896–97. There was, however, a falling off in several of the districts, especially in Sibsagar where the operations were fewer by 8,259. The largest increase occurred in Goalpara district (7,616), followed by Nowgong (6,452). Of the total operations 272,713 were primary cases, and of these 99·11 per cent. were reported as successful. The Compulsory Vaccination Act was in force during the year in 11 places, their population being 71,128. The number of infants successfully vaccinated was 58,455, representing only 25·9 per cent. of the births, estimated at 40 per 1,000 of the population.

Iadras. The aggregate number of vaccinations performed in the Madras Presidency during 1897–98 was 1,271,729, being an increase of 24,009 on the operations of the previous year. Of the total, 1,189,146 were primary cases, of which 92·0 per cent. were successful, against 92·5 per cent. in 1896–97. The number of children under one year of age successfully vaccinated rose from 330,819 to 331,297, which represented only 23·2 per cent. of the estimated births, being the same percentage as in the previous year. Vaccination is compulsory in all municipalities, and the number of operations performed by municipal vaccinators rose from 118,655 to 127,724. In the town of Madras the number of operations performed was 33,082, an increase of 6,061 on the previous year, which was chiefly due to the prevalence of small-pox in an epidemic form during the latter part of the year. Of the 21 districts there was an increase of work in 11, the most marked case being that of Ganjam (20,644). The largest decrease was shown in Vizagapatam (15,225), which is the more unsatisfactory as in the previous year Vizagapatam showed the largest increase (22,844). All the operations were performed with animal lymph, and the best results were obtained, as usual, from calf-to-arm vaccination, with a percentage of success of 95·5 against 94·7 in the previous year.

3ombay. Plague and famine greatly interfered with vaccination work in Bombay Presidency. In many parts the people were on the move and not readily got at, and from many of the large towns there was a considerable exodus ; the death-rate was also especially high among children, and there was a low birth-rate. Omitting the statistics of five Native States which are not under the supervision of the Vaccination Department, the out-turn of vaccination work in the Presidency fell from 810,723 operations in 1896–97 to 744,650. This shows the large decrease of 66,073 or 8·87 per cent. The total primary cases fell from 736,511 to 681,839 ; the percentages of success being respectively 93·69 and 91·84. The substitution of animal for human lymph continued to increase in the Presidency. In the City of Bombay vaccination with animal lymph exclusively was carried on throughout the year. Of the 626,170 primary successful cases, nearly 81 per cent. were infants under one year of age. Reckoning the births at 40 per 1,000 of population, 55 per cent. were protected from small-pox. Inoculation was not practised anywhere in the Presidency during the year, and no instances were reported of any disease having been communicated through vaccination.

3erar. Vaccination work continues to advance in Berar. During 1897–98, 125,289 operations were performed, against 120,111 in 1896–97. The increase, however, was entirely under revaccinations as the primary vaccinations fell from 98,594 to 95,048 ; and the percentage of success from 96·8 to 96·4. Of the total number of successful primary operations, 73,534 were performed on infants under one year of age ; estimating the births at 40 per 1,000 of population, 63·4 per cent. were protected from small-pox. The decrease in primary vaccination was attributed to the very high mortality among children in consequence of

the scarcity and distress that prevailed during the year. The Sanitary Commissioner continues his statement showing the efficacy of vaccination in checking small-pox mortality in Berar ; the ratio of successful vaccinations per 1,000 of population has risen from 8·92, the mean of five years 1868-69 to 1872–73, to 33·6, the mean of five years ending 1897–98 ; the mortality from small-pox for the same periods has declined from 2·02 to 0·19 per 1,000. " It may be noted," the Sanitary Commissioner states, " that small-pox " inoculation never prevailed in Berar, and that the disease is quite as virulent amongst " the unvaccinated as it ever was. There is nothing but vaccination to which this great " diminution of small-pox mortality can be attributed. The above figures tend to prove " the axiom that in countries where there is much vaccination and re-vaccination " relatively to the population there is but little small-pox." The Vaccination Act is now in force in all the municipal towns.

VI.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

The following comparative statement shows the number of hospitals and dispensaries open in the several provinces of India during 1897 and the previous year, and the number of patients under treatment :—

Provinces, &c.		Number of Institutions.	Number of In-door Patients.	Number of Out-door Patients.	Total Number of Patients.
Bengal	1897	477	55,644	2,778,468	2,834,112
	1896	455	47,109	2,637,501	2,684,610
Calcutta and Howrah	1897	16	28,955	260,806	289,761
	1896	16	25,647	258,794	284,441
North-Western Provinces and Oudh	1897	355	56,936	3,635,480	3,692,416
	1896	350	62,441	3,892,918	3,955,359
Punjab	1897	265	52,381	3,241,543	3,293,924
	1896	267	52,877	3,070,117	3,122,994
Burma	1897	99	34,102	754,458	788,560
	1896	96	30,929	677,560	708,489
Central Provinces	1897	121	14,170	1,512,489	1,526,659
	1896	95	13,527	1,360,602	1,374,129
Assam	1897	101	7,222	602,268	609,490
	1896	101	6,554	562,142	568,696
Coorg	1897	7	1,832	49,970	51,802
	1896	7	1,245	43,902	45,147
Madras	1897	480	63,130	4,247,138	4,310,268
	1896	489	56,625	4,189,762	4,246,387
Bombay	1897	323	47,763	1,766,783	1,814,546
	1896	325	47,090	2,373,637	2,420,727
Berar	1897	47	6,789	318,977	325,766
	1896	46	4,500	340,134	344,634
TOTAL	1897	2,291	368,924	19,168,380	19,537,304
	1896	2,247	348,544	19,407,069	19,755,613

Bengal.

There was a further increase in the number of charitable dispensaries in Bengal in 1897, and in the patients under treatment in them, as compared with the figures of the previous year. The total number of dispensaries at work during 1897 in Bengal, exclusive of the medical institutions at Calcutta, was 477, an increase of 22 on the number of the preceding year. At these there were 2,834,112 patients under treatment, 55,644 being in-door and 2,778,468 out-door patients, against 47,109 and 2,637,501 respectively in the previous year. This shows a total increase of 149,502, which was chiefly due to the famine which prevailed during the year, to the opening of new dispensaries, and to the increasing popularity of the institutions. Compared with other provinces, however, Bengal shows the lowest number of patients per dispensary. "The increase in the number of cases "treated in 1897," it is stated, "would perhaps have been even greater than it was, were "it not for the fact that towards the latter part of the year people were afraid to attend "dispensaries owing to the plague scare which followed the publication of plague "regulations."

There was again a satisfactory increase in the number both of women and children patients. The increase among women amounted to 35,432, the number having risen from

423,238 to 458,670. Of the diseases under treatment at the dispensaries, cholera, dysentery, and diarrhœa, and malarial fevers were responsible, as usual, for the largest number of cases. From malarial fever the cases rose from 506,757 in 1896 to 536,428, equal to nearly 19 per cent. of the total number of patients; next came dysentery and diarrhœa with 166,516 cases, against 137,568 in 1896, and from cholera the number of cases rose from 14,388 to 16,845. Cases of venereal diseases rose from 64,218 to 72,507. The number of deaths among in-door patients rose from 5,487 or 116·4 per 1,000 of total treated in 1896 to 8,172 or 146·8 in 1897. Great attention is paid in these institutions to surgery, and during the year 135,505 operations were performed, against 124,067 in 1896, and of these 216 terminated fatally. The more important operations numbered 3,596, of which 2,718 were extractions of the lens.

The following statement shows the number of in-door and out-door patients treated in the several hospitals and dispensaries in Calcutta and Howrah during 1897 and the previous year :—

Name of Institution.	1897.				1896.			
	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.
Medical College Hospital	4,672	36,424	41,096	121·0	4,485	35,457	39,942	118·6

The figures for 1897 show an increase of 2,012 in out-door patients, and of 3,308 in in-door patients. The death-rate for all the hospitals was 160·9 per 1,000 of the total in-patients, against 140 in the previous year. The admissions to hospital from cholera rose from 1,007 to 1,200, and 664 cases were fatal. Small-pox was more prevalent in Calcutta than in the previous year, and the cases admitted to hospital rose from 57 to 218. Of these, all but one were treated in the Campbell Hospital,and 56 cases were fatal. Dysentery was more general, and the number of patients rose from 7,778 to 8,415. The number of persons treated for diarrhœa was also larger, viz., 9,836 against 8,020. On the other hand, the number of cases of malarial fever fell from 48,982 to 46,025. Venereal diseases show an increase of 307 patients, the number treated having risen from 14,216 in the previous year to 14,523. There were 25,745 surgical operations performed, and death ensued in 178 cases, against 24,067 and 160 respectively in 1896.

North-Western Provinces and Oudh.

During 1897 there were 355 hospitals and dispensaries at work in the North-Western Provinces and Oudh, or five more than in the previous year. The number of patients who received medical aid was 3,692,416, against 3,955,359 in 1896. There was thus a decrease in 1897 of 262,943, which was principally due to the famine, on account of which a larger number of persons (726,929 as compared with 83,814 in 1896) was treated in famine relief hospitals and poor houses during the year. It is stated that only in two hospitals (the Colvin Hospital at Allahabad, and the Prince of Wales' Hospital at Benares) did the

daily average number of in-door patients exceed to any considerable extent the number of beds available. Of the total number, 53·38 per cent. were men, 22·38 per cent. were women, and 24·24 per cent. were children, the two former showing a small increase on the figures of the previous year, which were 51·48 and 21·42, respectively. The in-door patients numbered 56,936, as compared with 62,441 in 1896, and among them there were 4,514 deaths, giving a death-rate of 79·2 per 1,000, against 3,704 or 59·3 in the previous year. Of the diseases for which the patients were treated 713,032 were suffering from malarial fevers, an increase of 132,280 on the number of 1896 ; cases of cholera fell from 4,190 to 3,585, and cases of diseases of the eye fell from 343,791 to 302,319. From venereal diseases there were 89,012 patients, against 83,765 in the previous year. The number of surgical cases fell from 206,299 to 168,538, of which 144,406 resulted in cure and 443 were fatal. Of the total operations 6,566 were for cataract, of which 81 per cent. were successful, as compared with 8,923 operations and a percentage of success of 84 in 1896.

Punjab. The number of dispensaries at work in the Punjab during 1897 was 265 or two less than in the previous year. Statistics, however, are furnished for 268 institutions, as the returns include those of three famine relief works dispensaries which were in existence for part of the year only. At these, 3,293,924 patients were under treatment, being an increase of 170,930 on the number of 1896. The increase, however, was entirely among out-patients, the in-patients being fewer by 496. Of the diseases for which patients sought relief there were 98 cases of cholera, being a decrease of 772 on 1896. Cases of malarial fever rose from 363,913 to 646,471. Diseases of the eye showed an increase of 2,007 cases, the number treated in 1897 being 382,041, against 380,034. From venereal diseases there were 30,919 cases under treatment, a decrease of 3,495 on the previous year's figures. Among the in-patients there were 2,489 deaths during the year, being in the ratio of 47·5 per 1,000 of the number treated, against a death-rate of 44·2 in 1896. In surgical work operations decreased from 193,370 in 1896 to 173,808. Of these, 164,164 were cured and 296 died. "Various causes," the Inspector-General states, "combined to lessen the "operations. On account of the disturbed state of the frontier, few patients crossed the "border into the neighbouring districts. In many places the pinch of scarcity was sufficient "to prevent people incurring even the small necessary expenditure attendant on a visit to, "and stay in, a hospital. In some places, also, the restrictions and inspections imposed on "travellers on account of plague prevented patients from coming freely to hospitals." There were 4,671 cataract operations, and of these 85·9 per cent. resulted in cure.

Burma. The number of dispensaries existing in Burma at the end of 1897 was 99, or three more than in the previous year. At these, 788,560 patients attended, as compared with 708,489 in 1896. In-door patients rose from 30,929 to 34,102, of whom 24,604 were cured, and 2,613 or 80 per 1,000 died, against 1,921 deaths or 60 per 1,000 in the previous year. The total number of Burmans treated was 465,498, equal to 59 per cent. of the total patients. Malarial fevers, as usual, headed the list of maladies under treatment, the number of cases being 130,180 against 126,085 in the previous year. Cholera was more active than in 1896, and the number of cases rose from 112 to 914, of which the majority were in the lower part of the province. Cases of venereal disease fell from 26,198 in 1896 to 24,758. Surgical work showed an increase of 4,879 operations, the number having risen from 14,737 to 19,616, this large increase being mainly due to the inclusion of hypodermic injections which had been omitted in previous years. The number of patients cured, after being subject to operation, was 18,758, and 101 died.

Central Provinces. The number of hospitals and dispensaries at work in the Central Provinces during 1897 was 121, or 26 more than in the previous year. The total number of patients rose from 1,374,129 to 1,526,659. The increase extended to both in and out door patients, the former having risen from 13,527 to 14,170, and the latter from 1,360,602 to 1,512,489. Among the in-patients there were 1,905 deaths or 134·4 per 1,000 of total treated. The increase in attendance, it is observed, would no doubt have been greater but for the establishment of poor houses and relief works on account of the scarcity, and at which 607,949 patients received medical treatment. As regards the different kinds of diseases, the most remarkable features were the large increase of cases of malarial fevers (47,713), "a fact which clearly shows the unhealthy character of the year," and the diseases which so often accompany want—dysentery, diarrhœa, and ulcers. From venereal diseases there was an increase of 6,899 cases. There were 35,102 surgical operations performed, against 23,176 in 1896. Of these, 33,040 resulted in cure and 60 in death. In the four previous years there had been a considerable increase in operations for cataract, viz., from

479 in 1893 and 949 in 1894 to 1,299 in 1895 and 1,508 in 1896 ; but in 1897 they fell to 964.

Assam.

In the province of Assam the number of dispensaries remained the same as at the close of the previous year, viz., 101, but there was a considerable increase in the number of patients treated, the total for 1897 being 609,490, against 568,696 in 1896. The in-patients numbered 7,222 as compared with 6,551, and of these 3,702 were discharged cured, 606 relieved, 1,117 discharged otherwise, and 1,512 died, the latter representing 209·4 per 1,000 of the total in-patients, against a ratio of 151·5 in 1896. The number of natives of the country treated as in-patients fell from 1,932 in 1896 to 1,772, but the number of foreigners rose from 4,622 to 5,450, mostly *ex*-tea-garden and *ex*-railway coolies, many of the latter being admitted in a moribund condition, which partly accounts for the increased mortality in the dispensaries during the year. Of the total number of persons who received medical aid, malarial fever accounted for 203,816 cases, including 8,459 suffering from kala-azar ; skin diseases other than ulcers 103,132, worms 83,371, dysentery and diarrhœa 35,634, and diseases of the digestive system 26,018. Cholera patients numbered 3,026, against 2,734 in 1896. Of surgical cases there were 13,335, of which 12,688 were cured and 41 were fatal.

Madras.

Exclusive of the hospitals in the Presidency town there were 466 dispensaries working in Madras at the close of 1897, or 9 less than in 1896. The results of the year were again satisfactory. There were 4,092,551 patients under treatment, as compared with 4,042,533 in 1896. There was thus an increase of 50,018. Of the 44,222 in-door patients, 26,716 were returned as having recovered fully under treatment, 9,045 as relieved, and 3,646 as otherwise discharged. The deaths numbered 3,557, representing a ratio of 80·4 per 1,000 of the total in-patients, against 64·4 in the previous year. Ulcers and diseases of the skin, diseases of the eye, diseases of the digestive system, malarial fevers, rheumatic affections, dysentery, and worms were the most common diseases under treatment during the year. Cholera existed in an epidemic form throughout the whole Presidency, and 23,500 cases were under treatment in the various hospitals and dispensaries. From venereal diseases there were 75,310 cases, against 71,654 in 1896. The surgical operations rose from 143,750 in 1896 to 150,766. Of these, 136,137 were cured and 201 terminated fatally.

The number of medical institutions in Madras town remained the same as in 1896, but the number of sick treated increased from 203,854 to 217,717. The in-patients rose from 17,605 to 18,908, and amongst them 9,103 cases were recorded to have been cured or perfectly recovered, 4,494 were relieved, 3,315 discharged otherwise, and 1,144 or 60·5 per 1,000 died, against a rate of mortality in 1896 of 52·4. Of the several diseases for which the patients were treated, malarial fever, diseases of the digestive system, skin, and respiratory system were, as usual, the most common. From cholera there were 119 cases, from dysentery and diarrhœa 8,645, and from venereal diseases 4,445, of which 1,493 were afforded in-door relief. The surgical work performed in 1897 compares favourably with that of the previous year, the operations having increased from 27,903 to 31,794. The results showed that 13,282 cases were cured, 4,311 relieved, and 133 were fatal.

At the Madras Voluntary Venereal Hospital, which is included in the above hospitals in the city, there were 558 female patients treated during 1897, a decrease of 78 on the number of the previous year. The Surgeon General reported that he could not account for the decline.

Bombay.

Excluding the 11 medical institutions in the City of Bombay, there were 312 hospitals and dispensaries working in the Presidency at the end of 1897. At these, 1,742,804 patients were under treatment, of whom 32,585 were in-door and 1,710,219 out-door patients, against 30,857 and 2,288,489 respectively in 1896. There was thus a total decrease of 576,542, which, it is stated, was partly due to the scare caused by the plague and partly to the temporary closure of several dispensaries in the Presidency, the hospital assistants attached to them having been withdrawn for plague duty. Malarial fevers, as usual, constituted by far the largest number of cases (281,641, or 16·2 per cent. of the total treated), still there was a decrease of 104,910 when compared with the figures of the previous year. Next to fever, eye and skin diseases and worms were the most common ailments. Small-pox cases were slightly more numerous, the number having risen from 480 in 1896 to 495 ; cholera cases fell from 5,879 to 5,741 ; dysentery cases were also less numerous ; and patients suffering from venereal affections fell from 30,482 in 1896 to 24,580 in 1897. Of the in-door patients, 22,228 were cured, 1,932 relieved, 2,255 discharged otherwise, and 4,762 died, the ratio of deaths to total treated being 146

per 1,000, more than double the ratio (72 per 1,000) of the preceding year. The total number of patients operated on was 82,352, as compared with 110,994 in 1896, and of these 70,566 were cured and 122 died.

The total number of patients treated at the 11 civil medical institutions working in the town of Bombay during 1897 showed a decrease of 29,639, the figures being 71,742, against 101,381 in the previous year. The in-patients decreased in number from 16,233 to 15,178, and of these 9,280 were cured, 2,048 relieved, 718 otherwise discharged, and 2,079 died, the deaths being in the ratio of 136 per 1,000 of the in-patients, against 106 per 1,000 in 1896. As usual, local injuries, malarial fevers, eye diseases, and skin diseases were responsible for the majority of the cases. Venereal diseases contributed 4,445 cases, against 4,799. Cholera cases rose from 6 to 8, those of dysentery fell from 1,509 to 1,384, and of diarrhœa from 3,454 to 2,795. The total number of patients operated on was 16,783, and of these 14,237 were cured, 146 relieved, 64 discharged otherwise, and 146 died.

Berar. There were 47 medical institutions at work in Berar during 1897, or one more than in the previous year. Of these, eight are hospitals wholly maintained by the State. The total number of patients under treatment was 325,766, against 344,634 in 1896. The decrease was entirely among out-door patients, as the in-patients rose from 4,500 to 6,789. The Inspector General states that the general effect of famine appears to have increased the in-door and decreased the out-door attendance. "Relief centres," he says, "attracted "the labouring classes whose physical condition enabled them to work, thus diminishing "the out-door attendance; whilst the physically unfit and wanderers suffering from chronic "starvation found their way into our hospitals." Of the in-patients, 5,134 were cured and 926 died, which gives a death-rate of 136 per 1,000, as compared with a mortality of 349 or 78 per 1,000 in 1896. Malarial fevers continued to head the list of diseases from which relief was sought, but the cases again fell from 71,822 in 1896 to 71,047; nearly a fourth of the total patients were treated under this head; diseases of the eye and skin came next in order. Cholera cases rose from 3,001 in 1896 to 4,226. There was a decline in surgical work; the total number of patients operated on being 10,538, against 11,412 in 1896. Of these, 10,429 were cured and 24 died.

The Dufferin Hospital for women and children at Amraoti, which was opened on the 15th February 1895, continued to work satisfactorily. The in-door patients during the year numbered 257, and the out-door 5,913, against 128 and 5,806 in the previous year. The operations rose from 161 to 182.

Lunatic Asylums.

Bengal. At the five asylums in Bengal (viz., Dullunda, Dacca, Patna, Cuttack, and Berhampore) 1,119 lunatics, including 201 fresh admissions and re-admissions, were under treatment in 1897, being an increase of 17 on the number of the previous year. In the course of the year under notice 64 patients were discharged as cured, and 42 as improved or otherwise, and 90 died. Compared with the figures of 1896, the number discharged was more by 12, while the mortality was about the same. At the end of the year there were 923 persons still under detention, or 5 more than at the close of 1896. The health of the inmates of the asylum was not so good as in the previous year, the average daily number of sick being 129, against 85 in 1896; but the number of admissions into hospital were fewer by 188. The mortality during the year was slightly lower than in the preceding year, the number of deaths having fallen from 90 to 89 and the death-rate from 98·4 to 97·0 per 1,000 of average strength. The results of the working of dairy farms at the asylums were not satisfactory. At Dullunda there was a loss of Rs. 1,134 as compared with a profit of Rs. 636 in the previous year, the reason given being "that a number of dry cows had "to be fed until they were disposed of, and in a year of scarcity the cost of up-keep of such "cows was very high." At Dacca the sale of milk to the public was discontinued, the whole of the produce being issued to the lunatics, the dairy therefore yielded no profit during the year. The dairy farm at Berhampore which was opened in the latter part of 1896 worked throughout the year, but the results were not as satisfactory as was expected.

In the Bhowanipur Asylum, containing European and Eurasian patients only, the inmates during 1897 numbered 55, against 51 in the previous year. Of this number 36 were under detention at the beginning of the year, and 19 were subsequently admitted. In the course of the year 6 patients were discharged cured, 10 were transferred

to the care of friends, and 4 died, leaving 35 under confinement at the close of the year. As regards the health of the patients during the year, there were only 8 admissions to hospital, and 4 deaths. The proportion of deaths to average strength was 107·0 per 1,000, against 150·9 in 1896.

North-Western Provinces and Oudh.

The inmates of the four lunatic asylums (Agra, Bareilly, Benares, and Lucknow) in the North-Western Provinces and Oudh in 1897 were 1,334, including 238 admissions during the year, against 1,322 in 1896. Before the close of the year 162 patients were discharged, of whom 119 were reported as cured, 43 were made over to friends, and 88 died, leaving 1,084 under treatment at the end of the year. The health of the asylum population was not so good as in the preceding year, and the death-rate per 1,000 of average strength rose from 54·5 to 78·4. Dairy farming was not so successful at Bareilly as in 1896. The profits decreased from Rs. 10,663 to Rs. 6,939, the falling off being attributable to temporary causes connected with high price of fodder and necessity of replenishing the stock. A scheme was initiated during the year for abolishing one of the smaller asylums, probably the Lucknow Asylum, and establishing a large central institution at Agra, under the charge of a whole-time Superintendent who will be able to devote his undivided attention to the asylum and its inmates. The matter was still under consideration at the close of the year.

Punjab.

The total number of lunatics in the Lahore and Delhi lunatic asylums in the Punjab during 1897 was 526, including 144 fresh admissions, against 495 in 1896. At the end of the year the number was reduced to 388 by the discharge of 106 patients (52 as cured, 26 made over to friends, and 28 otherwise discharged) and 32 deaths. In both asylums there was more sickness among the inmates than in the previous year, and the mortality was much higher. The total number of hospital cases was 546. In Lahore the cases rose from 367 in 1896 to 498, and the deaths from 18 or 76·6 per 1,000 of daily average strength to 21 or 81·5. In the Delhi Asylum the deaths numbered 11 or 85·8 per 1,000, against 4 or 33·9 in 1896. No special diseases were present in any unusual degree, and there was a satisfactory falling off in the number of pneumonia cases at Lahore, which was attributed largely to the increased material comforts of the inmates. In the Delhi Asylum, on the other hand, pneumonia prevailed somewhat.

Burma.

The Rangoon Asylum is the only one in the province of Burma. Until the year 1894 a number of lunatics were, for want of accommodation, confined and treated in the Rangoon central jail. The asylum has since been twice extended, and there is now accommodation for 414 insanes. During 1897 there were 448 patients in the Rangoon Asylum, including 115 fresh admissions, and the total was reduced at the close of the year to 342 by the discharge of 70 patients for different causes, and the death of 36. Although the daily average sick was much lower than in 1896, the admissions to hospital rose from 104 to 155. No epidemic disease occurred among the patients, but the deaths rose from 30 or 90·3 per 1·000 of average strength to 36 or 108·0. Four of the deaths occurred within the first month, and 3 more within the second month of residence in the asylum, all of whom were civil lunatics. Of the 448 insanes 202 were criminal lunatics, and among them were 10 deaths as compared with 26 among civil lunatics, the high mortality among the latter being attributed to their general bad state of health on admission.

Central Provinces.

In the two asylums of the Central Provinces (Nagpur and Jubbulpore), there were 382 lunatics under treatment during 1897, the same number as in 1896. In the course of the year 44 patients were discharged as cured or otherwise, and 27 died, leaving 311 still under treatment at the commencement of 1898. Both asylums were less healthy than in 1896. The admissions to hospital at Nagpur rose from 50 to 59, but at Jubbulpore they fell from 109 to 108. The chief cause of sickness was, as usual, ague, from which there were 21 admissions at Nagpur, and 35 at Jubbulpore. At both asylums the mortality was higher as compared with the previous year. Of the total 27 deaths, Nagpur recorded 14, being in the ratio of 83·7 per 1,000 of average strength, against 7 or 39·4 in 1896. At Jubbulpore there were 13 deaths, being in the ratio of 86·2 per 1,000, against 11 or 71·3 in 1896. A dairy farm was started in 1895 at Nagpur Asylum, and it has continued to give excellent results both financially and in regard to the health of the inmates.

Assam.

There is only one lunatic asylum in the province of Assam. This is situated in Tezpur, and the building is reported to be at present large enough for all demands on it. The total number of lunatics under treatment in the asylum during 1897 was 153, the same number as in the previous year. Of these, 27 were fresh admissions. At the close of the year the patients in the asylum were reduced to 118, 24 of the total number having

been discharged, 10 died, and one escaped. Although the year was an unhealthy one in the district, there was less sickness in the asylum, but the mortality was higher. Among the 153 inmates 92 were admitted to hospital, as compared with 130 in 1896. The number of deaths was greater by three than in 1896, and the death-rate rose from 60·1 per 1,000 of average strength to 81·6. Three of the deaths were from phthisis, and two from dysentery.

Madras. At the commencement of 1897 there were 584 patients under treatment in the three lunatic asylums (Madras, Vizagapatam, and Calicut) of the Madras Presidency. During the year 158 fresh cases were admitted, bringing the total population up to 742, or 22 less than the number in the preceding year. In the course of 1897 there were 103 cases of discharge, and of these 61 were cured. The accommodation was ample, and there was no overcrowding in any of the asylums during the year. On the whole there was less sickness among the patients than in the previous year ; the daily average sick fell from 87 to 78, while the deaths rose from 46 or 77·7 per 1,000 of average daily strength to 59 or 100·5. No epidemics occurred in the Madras and Vizagapatam Asylums, but cholera appeared in the Calicut Asylum, and the necessary steps for segregating the patients and preventing the spread of the disease were taken. Of the total 59 deaths the Madras Asylum contributed 37, giving a death-rate of 87·8 per 1,000 on an average strength of 421, against a ratio of 89·6 in 1896. The death-rates of the other two asylums, Vizagapatam and Calicut, were 14·0 and 223·4 per 1,000 respectively, against 14·9 and 69·2 in the previous year. In the Calicut Asylum there were 21 deaths, and of these 8 were due to cholera.

Bombay. The total population of the six lunatic asylums of the Bombay Presidency (Colaba, Ratnagiri, Poona, Dharwar, Ahmedabad, and Sir Cowasji Jehangir, Hyderabad) was 1,029, including 293 fresh admissions, chiefly mendicants and beggars, against 1,006 in 1896. In the course of the year 187 patients were discharged, 81 of them as cured, and 81 died, leaving 761 under treatment at the close of the year. There was slightly more sickness in the asylums than in 1896, the daily average sick having increased from 47 to 49, the deaths also rose from 78 to 81, but owing to the increase in the daily average strength the death-rate fell from 107·8 to 105·9. Of the 81 deaths, 22 were due to dysentery, 12 to phthisis, and 7 to Bright's disease. The death-rate was higher in all the asylums, excepting Colaba and Ahmedabad. The Colaba Asylum recorded the highest mortality, viz., 168·4, but this was 17·2 per 1,000 lower than the ratio of 1896.

Medical Schools.

Bengal. The number of medical schools open in Bengal during 1897–98 was 9. The Medical College, Calcutta, and four of the medical schools are maintained by Government, the rest are unaided—two being schools of homœopathy, and two of allopathy. The college is affiliated to the University, and prepares candidates for its various medical degrees. The four Government medical schools train pupils as Civil Hospital Assistants, and the four unaided schools follow their own standards for private practice. The total number of pupils attending the various medical schools in the province was 1,815, as compared with 1,950 in the previous year.

The number of students at the Calcutta Medical College at the beginning of the session in 1897–98 was 583 (including 16 women), against 588 in the preceding year. As regards the examinations, 194 candidates were successful out of a total of 440 (including 1 woman), the successes being at the rate of 44 per cent., as compared with 55 per cent. in 1896–97. Of the 194 successful candidates, 61 passed the Preliminary Scientific L.M.S. examination, 53 passed the first, and 33 the second L.M.S. examinations ; 18 passed the Preliminary Scientific M.B. examination ; five passed the first and three the second M.B. examinations ; 15 native dais passed in midwifery from the Eden Hospital, and received certificates of qualification, and 14 pupil nurses also passed as midwives.

The Campbell Medical School had 301 pupils (including 34 women) on its rolls during the session. Of this number 56 males and 9 women passed the final examination for the diploma.

At the Dacca Medical School there were 169 pupils on the rolls (including 10 women). Thirty-eight students (including one woman) passed the final examination.

The Temple Medical School, Patna, had 133 students (including 4 women) on its rolls. At the final examination 28 candidates passed, including two women.

At the Cuttack Medical School there were altogether 114 pupils (including five women). At the final examination 31 candidates (including two women) passed.

North-Western Provinces and Oudh.

The number of pupils of the various classes of the Agra Medical School who attended the examination at the close of the year 1897–98 was 259 (including 59 women), as compared with 252 at the end of the preceding year. The results of the final examination of male students show that 43 out of 52 candidates passed. All the 6 military students in this class passed, and 34 of the 41 civil students passed. Of the students in Class II., comprising second-year military and third-year civil, private, and Rajputana pupils, 11 out of 15 military pupils and 22 out of 27 civil pupils passed the first half professional examination. All classes of pupils are reported to have done better in the year under notice than in the previous year, their average marks being higher all round.

As regards women students, the year's working shows that 10 out of 15 in Class I. passed the final examination, and that 7 out of 17 in Class II. passed the first half professional examination.

Punjab.

The total number of students at the Lahore Medical College and School during 1897–98 was 415, or 50 less than in the previous year. Of these, 210 were in the College Class, and 205 were in the Medical School. There was a decrease of 37 in the number of college students, which was due to the introduction of a higher standard of attainment as a condition of admission. The results of the year's examinations were less favourable than in the previous session. Six students appeared at the first examination for the M.B. degree, and two passed, and 60 at the first L.M.S. examination, of whom only 20 or 33 per cent. passed. In the second L.M.S. examination 13 passed out of 34, and in the second M.B. examination three candidates appeared and all passed.

In 1894 a medical school for women, called the North India Medical School for Christian Women, was opened at Ludhiana. The object of the institution is "to provide a thorough "medical training, under fully qualified Christian women, for those Christian women and "girls who wish to prepare themselves for medical mission work." At the end of 1897 there were 20 students on the rolls, or 4 less than in the previous year, and they were reported to be making satisfactory progress.

Madras

The number of students at the Madras Medical College (including the School Department) during 1897–98 was 478, including 33 women students. In the Hospital Assistant Department, consisting of 206 pupils, 57 appeared for the final examination, of whom 39 passed. The results of the several University examinations were again satisfactory, 32 having passed out of 63 candidates entered, against 42 out of 65 in 1896–97. In the College Department there were, as in the previous year, 41 (including one woman) regular students reading for the M.B. and C.M. degree, 26 (including one woman) reading for the L.M.S. degree, and 16 casual students.

The Board Medical School at Nellore having been closed, the only other medical school at work during the year was the Prince of Wales' Medical School, Tanjore. At this there were 47 pupils on the rolls, all of whom were being prepared for the Hospital Assistants' Certificate. Six candidates appeared for the final examination and all passed.

Bombay.

The attendance at the Grant Medical College, Bombay, rose from 279 in 1896–97 to 320 (including 26 women) in 1897–98. For the first University examination in medicine 120 candidates presented themselves, of whom 41 qualified; and for the second examination in medicine 37 passed out of 71 candidates. For the final examination for the degree of L.M.S there were 36 candidates, and of these only 11 passed, all in the second class. Out of a total of 41 military medical pupils 10 passed their final examination. A number of the students were deputed to assist in the examination of persons leaving Bombay by sea, and also in house to house visitations on account of the plague, and the Principal testified to their behaviour and courage in the execution of these duties.

The Government Medical Schools at Poona, Ahmedabad, and Hyderabad continued to work satisfactorily. The number of students was 214, and of these 52 passed the final examinations.

VII.—SANITATION.

Bengal.

In Calcutta further progress was made in the improvement of bustees, or clusters of Native huts. The supply of filtered water was slightly less than in 1896, and the average daily consumption was equal to 38·10 gallons per head of population for the town proper, and 11·26 gallons for the suburban area. In the course of the year the distribution pipes were extended about 2½ miles, bringing the total length up to nearly 315 miles, and the total number of premises connected had reached 27,775. The supply of unfiltered water was rather higher, and the daily consumption per head of population was equal to 12·51 gallons, as compared with 12·47 gallons in 1896. A scheme for the extension of the unfiltered water supply was carried out during the year and completed in March 1898, the result being an extension of the water main by over 15½ miles, bringing the total length of pipe up to 96½ miles. A second project for extending the unfiltered water supply to the suburbs was also being carried out. At the close of the year (1897–98) the total length of sewers was a little over 209¼ miles, and the number of premises connected with them was 29,848, of which 260 connections were made during the year. Satisfactory progress was made with the new drainage project for the municipality. Further improvement was made during the year in the conservancy of the port of Calcutta.

The total amount spent on sanitary works in urban and rural areas during the year was Rx. 209,934, a decrease of Rx. 33,757 on the sum expended in the previous year. Of the total Rx. 53,160 were spent in towns and Rx. 156,774 in rural areas. In addition, a further sum of Rx. 116,747 was contributed by private individuals for the same purpose, the latter item showing a satisfactory increase. The most important works were the completion of the Bhagalpur water supply at a cost of Rx. 27,096, commencement of work on the Berhampore water supply, and the extension of that of Cossipur-Chitpur. A drainage scheme for the latter municipality and for that of Maniktola were under consideration, and the Krishnagar scheme has been adopted. The Howrah scheme, which was prepared by the engineer of the Calcutta Corporation, was found too expensive, and has fallen through.

The Sanitary Board held meetings in the course of the year, when, among other important matters, they discussed the Howrah drainage scheme and the drainage of the suburbs of Calcutta. Under the orders of the Government the Board prepared a water-supply scheme for the Garden Reach Municipality, estimated to cost Rx. 5,000, and another for Darjeeling, to cost Rx. 11,000. For the Patna Municipality a road drainage scheme was prepared, estimated to cost Rx. 5,600. Experimental borings for water were carried out with great success at Patna, and it is in contemplation to substitute the river Sone for the Ganges as the source of the town's water supply.

North-Western Provinces and Oudh.

In the North-Western Provinces and Oudh the municipalities expended over 41 per cent. of their income on water supply, drainage, and conservancy. In most of the municipalities possessing waterworks, house connections were extended, and the quality of the water was good. At Allahabad work was commenced in extending the filtered water-supply to Daraganj and in the completion of the sewerage of the City of Benares. "Both works," the Army Sanitary Commission observe, "are of the utmost "importance in their bearing on the health conditions of the two cities subjected to special "danger from importation into them of disease by pilgrims from all parts of India." Reservoirs were begun at Naini Tal, for which town a comprehensive scheme is in course of preparation. At Benares and Mussoorie drainage projects were in progress. The chief work of the year lay rather in village improvements in connection with famine relief, and in the measures taken for the prevention of plague. The Sanitary Commissioner reports that the principal towns of the provinces have never been, during the last 20 years, in so satisfactory a sanitary condition as they are at present. The Village Sanitation Act, which had been found useful in certain districts to which it had been tentatively extended, was in 1896 brought into force throughout the provinces.

Two meetings of the Sanitary Board were held during the year under report. From lists forwarded to the Government by the Sanitary Board it appears that, between 1889 and 1896, 255 drainage projects have been completed by the Irrigation Department at a cost of Rx. 117,413, while on the 1st April 1896, 50 works were in progress at an estimated

cost of Rx. 43,500. The programme for 1897 and the two following years comprises the construction of 104 drainage works at a cost of Rx. 54,681, these being arranged by districts in order of urgency.

Punjab.

In the Punjab the municipal towns spent 23 per cent. of their income on sanitary work. During the year the water-supply scheme of Pind Dadan Khan, in the Jhelum district, was completed, as was also the water supply for the cavalry lines at Kohat. The water-supply projects of Bhiwani, Peshawar, and Edwardesabad were in progress, and those of Amritsar, Ludhiana, and Mooltan, the extension of the Delhi supply, and the supply of the Mian Mir cantonments from Lahore, were under preparation. In Delhi a portion of the drainage scheme has been completed, and the remainder is under preparation. Drainage projects for Mooltan, Rawalpindi, Hazro, and other towns were in progress, while Rx. 7,800 were spent on the works at Lahore, and Rx. 1,060 on drains at Peshawar. Besides these, several works of public utility were constructed by private individuals at their own expense to serve sanitary purposes.

The Sanitary Board met once during the year, when they considered, among other matters, the prevalence of fever in the province, specially in swampy and water-logged areas, and the remedies that might be applied ; and suggestions concerning the unhealthiness of certain villages in the Umballa district.

Burma.

The towns and districts of Burma spent over 33 per cent. of their income on sanitary improvements. No important work was undertaken during the year, but municipal committees are reported to have devoted a considerable share of their attention to the subject, and expenditure was incurred on the preliminary experiments and surveys which are necessary before a mature scheme can be elaborated. A Sanitary Engineer has been appointed for the province, and was employed during this year in examining a scheme for supplying water to the town of Moulmein. In Rangoon experiments carried out by private individuals, with a view to testing the efficiency of tube wells as a permanent source of water supply, appear to have met with success, and it is in contemplation to adopt this system. Schemes for improving the water supply were being considered by the municipal committees of Bassein and Prome. The village sanitary rules which were issued in 1895 were working well, and in many cases resulted in improvements in drainage and conservancy.

The work of the Sanitary Board was again restricted to the provision of suitable sanitary maps of the larger towns. Complete maps have now been made for 15 towns and others were in preparation.

Central Provinces.

The municipalities in the Central Provinces expended 18 per cent. of their income on conservancy, drainage, and waterworks. The most important works undertaken or in progress were schemes for supplying water to certain municipalities. The Jubbulpore waterworks were further extended during the year, and were nearing completion. The Khandwa works were practically completed, and progress was being made with those at Wardha ; but the Harda scheme has been temporarily postponed for want of funds. The system of village sanitary inspection books has been introduced in several districts, but little progress was made in filling them in with the information required, owing to the heavy duties falling on civil surgeons in connection with the famine and plague. The Village Sanitation Act of 1889 was extended to one additional village during the year.

The Sanitary Board met in each of the four divisions during the year, when proposals and estimates for schemes of sanitary improvement in the various districts were considered.

Assam.

Excluding the towns of Hailakandi, Sunamganj, Karimganj, and Maulvibazar, which have no separate incomes of their own, the municipalities, stations, unions, and towns in Assam spent 44 per cent. of their income on sanitation. No extensive sanitary work was undertaken during the year, but the waterworks at Gauhati and Shillong, which suffered from the earthquake, were under repair. The sanitary improvements effected in rural tracts were comparatively unimportant, though some progress was made in the direction of providing a purer water supply by the construction of masonry wells and the excavation of tanks at some of the larger villages.

No meeting of the Sanitary Board was held during the year ; but the opinions of the members on important sanitary matters under discussion were obtained unofficially.

Madras.

In Madras Presidency the municipal councils allotted 63·6 per cent., and the district boards 8·4 per cent., of their income for sanitary purposes. During the year the water-supply works at Conjeeveram and Kurnool were completed, the latter being designed to

supply 15 gallons per head *per diem* to a population of 30,000 ; while those of Coconada, Tirupati, and Vizagapatam were in progress. Village sanitary inspection report books were in use in all unions in 19 out of the 22 districts of the Presidency at the end of the year, the exceptions being Malabar, Anantapur, and Tanjore.

The Sanitary Board during 1897 scrutinised plans and estimates for 185 sanitary projects, aggregating in value nearly 12 lakhs of rupees, of which 54 were for municipalities and 131 for local fund boards.

The Sanitary Engineering Department completed surveys for water supply or drainage for two municipalities, and one scheme was still under consideration. Four schemes, costing Rx. 167,700, were submitted to the Sanitary Board, the most important being the water-supply scheme for Negapatam, estimated to cost 10 lakhs, and a drainage scheme for Cuddapah, to cost $5\frac{1}{2}$ lakhs. The latter, as well as a water-supply scheme for Tuticorin and a drainage project for Ootacamund, was under consideration of Government at the end of the year. Preliminary reports were also made regarding the water supplies of Ellore, Conjeeveram, Trichinopoly, and Cuddapah (extension) ; the estimate for the Coconada works was revised, and other minor estimates made. Eleven out of the 58 municipalities in the Presidency now possess public water-supply and drainage works, and of these nine were executed by the Sanitary Engineering Department during the seven years it has existed.

In improving the sanitation of Madras City several useful improvements were being carried out. The water supply was extended, and a project estimated to cost nearly 16 lakhs was submitted to Government. The long-contemplated scheme for the drainage of the city has been taken in hand, the Commissioners having now almost finished the drainage of Mylapur. But it will be several years before the drainage scheme is completed, and until this is done, and the proposed improvements in the water supply are effected, Madras cannot be expected to become a healthy town.

Bombay. In Bombay Presidency the municipalities, exclusive of Bombay City, allotted 57·21 per cent., and the district boards 20·84 per cent. of their income for sanitary purposes. During the year improvements to the waterworks at Hyderabad, Surat, Ahmednagar, and Jacobabad were executed ; while those at Yeola, Sukkur, and Karachi were practically completed. At Ahmedabad one-fifth part of the sewerage scheme drawn up by Mr. Baldwin Latham was completed, and has proved so satisfactory that it was intended to extend it to the rest of the city. There was not, however, satisfactory progress in sanitary works during the year, owing to the demands on municipal funds caused by the plague. The Bombay Village Sanitation Act of 1889, under a modified form, has been brought into force in all the districts except Kanara and Upper Sind Frontier.

The Sanitary Board gave advice concerning a large number of projects, including the waterworks of Malegaon in Nasik district, and Sholapur, the sewage farm at Hyderabad, and other sanitary schemes which had been submitted to them. The water supply and drainage of Poona and Nasik are still unsatisfactory.

In Bombay City the Shone system of sewerage at Colaba worked satisfactorily during the year, and the sewerage of Mazagon on the same system has been started. In other divisions drainage and sewerage works were in progress, while several new works were commenced. The water supply of the city from Tansa, Vehar, and Tulsi lakes continued to be adequate ; structural and other improvements in the reservoirs were being carried out.

Berar. The municipalities of Berar spent 71 per cent. and the district boards about 16 per cent. of their income on sanitary improvement. No new works of any great importance were undertaken during the year, but Rx. 2,500 were spent on repairs to the Khamgaon tank, and a drainage scheme for Amraoti was under consideration ; while in the latter town specially active measures were also taken to guard against plague.

The District Sanitary Boards met once at each of the six headquarter stations. The Medical Department of the province was much occupied in supervising famine relief camps, and the sanitary survey did not make much progress during the year. The total of towns and villages surveyed up to date is 918. The Sanitary Commissioner states that sanitary progress has been steady, though slow, and that the people have generally appreciated improved water supply, drainage, or conservancy.

W. T. Ronson.

India Office,
October, 1899.

ABSTRACTS

OF

SANITARY AND OTHER REPORTS

FOR

1897.

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1897.

(*Surgeon-General Robert Harvey, M.D., C.B.*)

European Troops.

Sickness and mortality in 1897.

THE health of the European army of India was much worse in 1897 than in the preceding year. This was due partly to the increase of malaria consequent on the prolonged drought being followed by an abundant monsoon, and partly to exposure and injury on field service.

YEAR.	Strength.	RATIO PER 1,000 OF STRENGTH.				
		Admissions into Hospital.	Constantly Sick.	Deaths.	Invaliding.	TOTAL LOSS.
1886–95	677,877	1,457	83	15·16	24	39
1896	70,484	1,387	94	14·84	28	43
1897	68,395	1,557	101	22·93	33	56

The chief causes of admission were venereal diseases and ague. Among the diseases with increased admission rates were cholera, fevers, dysentery, and diarrhœa. On the other hand, the admission rates from influenza, small-pox, respiratory diseases, hepatitic diseases, and venereal diseases, were lessened. Venereal diseases caused 31 per cent. of the total sickness, and ague 25 per cent.

The chief causes of death were enteric fever, dysentery, abscess of the liver, and cholera. Among the diseases with increased mortality were dysentery, diarrhœa, cholera, enteric and other fevers, heatstroke, hepatic abscess. On the other hand, the mortality from small-pox and diseases of the respiratory organs was lessened. Enteric fever caused over 39 per cent. of the total deaths, dysentery 11 per cent., hepatic abscess nearly 6 per cent., and cholera over 5 per cent.

The chief causes of invaliding were, in order, syphilis and gonorrhœa, debility, malarial fevers, and tubercle of the lungs.

In the following Table the ratios of the four commands are placed side by side for comparison. Bengal had the highest mortality from cholera, heatstroke, and hepatic abscess; the Punjab the highest from small-pox, enteric fever, ague, remittent fever, tubercle of the lungs, pneumonia, other respiratory diseases, and dysentery; Madras the lowest from enteric fever and pneumonia; and Bombay the lowest from ague, heatstroke,

and dysentery. The percentage of enteric fever was highest in the Punjab ; of dysentery in Madras ; of hepatic abscess and cholera in Bengal. The total death-rate of Madras, which was the lowest, only reached 56 per cent. of the height of that of Bengal, which was the highest. Bengal had the highest constantly sick, admission, and death-rates, and all the commands were less healthy than in the previous year.

Ratios of Commands.

	Ratio per 1,000 of the Average Strength.				
	Bengal Command.	Punjab Command.	Madras Command.	Bombay Command.	India.
I.—Strength	20,113	17,190	12,369	14,859	68,395

All Causes	23·32	21·52	13·10	14·33	22·93

The following table gives vital statistics of the European troops in Burma as a whole :—

Period.	Strength.	Ratio per 1,000 of Strength.				
		Admissions into Hospital.	Constantly Sick.	Deaths from		
				Cholera.	Other causes.	Total.
1890	4,712	1,743	·102	—	20·80	20·80
1891	4,623	1,589	92	2·38	17·74	20·12
1892	4,316	1,491	91	—	14·83	14·83
1893	3,928	1,461	96	·25	12·73	12·98
1894	3,940	1,465	93	·25	9·39	9·64
1895	4,045	1,410	96	·99	8·41	9·39
1896	4,174	1,514	109	·48	6·71	7·19
1897	4,060	1,467	107	—	10·84	10·84

Burma in 1897 was distinguished by the prevalence of influenza, remittent fever, simple continued fever, and venereal diseases.

Of the forces which took the field in 1897, the Tochi Force, which was for the most part condemned to inactivity in the trying Tochi Valley, was the most unhealthy, suffering severely from dysentery, diarrhœa, enteric fever, remittent fever, and ague. Next came the Tirah Force, whose statistics were unfavourably influenced by severe fighting; followed, in order, by the Malakand, Kohat-Kurram, and Mohmund Forces.

The following table shows that, judging by the constantly sick-rate, Burma Inland and the Gangetic Plain were the most unhealthy groups for the decennium, and the Hills and the Deccan the most healthy. It also shows that the 1897 constantly sick-rate of every group, except the Western Coast, was higher than its corresponding decennial ratio, and that the rise was greatest in the case of Central India, the Burma Coast, the Hills, and the Deccan. As compared with the decennial ratios, there was decrease of cholera mortality in eight groups, and increase of enteric fever mortality in nine :—

In the following table the vital statistics of the groups for 1897 will be found placed side by side to facilitate comparison. Central India had the highest constantly sick, admission, and death rates; the Western Coast the lowest constantly sick-rate; the Hill Convalescent Depôts the lowest admission-rate; and the Burma Inland group the lowest death-rate. Burma Coast had the highest admission-rate from influenza and venereal diseases; Burma Inland the highest from remittent fever and simple continued

fever; Bengal-Orissa the highest from respiratory diseases other than pneumonia, dysentery, and hepatic abscess; Gangetic Plain the highest from cholera and small-pox; Indus Valley the highest from ague and pneumonia, the Convalescent Depôts being equal in pneumonia; Central India the highest from enteric fever and diarrhœa; the Deccan the highest from tubercle of the lungs; Southern India the highest from congestion of the liver; and the Hills the highest from rheumatic fever.

The percentage of enteric fever to total admissions in 1897 was greatest in the Hills; of ague in the Indus Valley; of remittent and simple continued fevers in Burma Inland; of pneumonia and hepatic abscess in the Convalescent Depots; of other respiratory diseases in Western Coast; of dysentery in Bengal-Orissa, where also hepatic abscess was nearly the highest; and of venereal diseases in Burma Coast.

The highest ratios among the large garrisons with a strength of over 1,000 were those of Agra, Peshawar, Meerut, Mhow, and Umballa, and all were higher than the corresponding ratios of 1896. All these stations had increased mortality from enteric fever; some, increased mortality from malarial fevers, from dysentery, from hepatic abscess. The health statistics of some stations, such as Cawnpore, Umballa, Dalhousie, Rawalpindi, and Thobba, are said by the medical officers to have been unfavourably affected either by the withdrawal of the healthy men for field service, or by the reception of broken-down men from field service.

The statistics of individual regiments show that the infantry had the highest admission and constantly sick-rate, as in the previous year; the artillery the highest invaliding rate, as in 1896; and the engineers the highest death-rate. The 1st Battalion, East Surrey Regiment, at Jhansi, had the highest constantly sick-rate, and it may be noted that it was a regiment at Jhansi which had the highest constantly sick ratio in 1896. The 1st Battalion, Shropshire Light Infantry, which suffered from cholera at Sitapur, and the 2nd Battalion, York and Lancaster Regiment, which suffered severely from enteric fever at Agra, had the highest death-rates.

Principal diseases: Influenza.—Sickness and mortality having been studied in their relation to India, to commands, to geographical groups, to stations, and to regiments, it will be convenient now to discuss the statistics of some of the chief diseases.

At the end of 1896 influenza was falling. In the course of 1897 there were three abrupt monthly rises,—in March, in June, and in October-November. The number of admissions fell suddenly again in December. The following shows the decrease of total in 1897. It also shows the monthly progress and the annual fluctuations of the disease since 1890, the first epidemic year:—

Period.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.	Per 1,000 of strength.
1890	—	3	473	1,451	248	69	13	2	3	—	—	1	2,263	33·4
1891	1	—	1	16	77	91	112	29	20	2	2	21	372	5·5
1892	113	53	354	241	57	4	32	8	—	—	—	—	862	12·7
1893	1	—	—	15	4	—	—	—	—	—	—	1	21	·3
1894	7	9	12	70	101	30	7	7	—	2	—	—	245	3·4
1895	14	7	52	156	66	35	17	1	5	13	23	165	554	7·8
1896	262	65	140	30	12	7	3	3	88	128	50	20	808	11·5
1897	12	10	31	9	11	30	8	8	—	54	87	12	272	4·0
Total	410	147	1,063	1,988	576	266	192	58	116	199	162	220	5,397	

The actual maximum of the individual years of the eight occurred in various different months, but over the eight-year period as a whole the greatest number of cases occurred in April and March, and the smallest number in August; 82 per cent. of the whole in the first six months of the year, and only 18 per cent. in the last six months. Geographical Groups I, II, V, VI, VIII, IX, XI, XII*a*, and XII*b* were attacked both in 1896 and 1897; Group VII, which had been affected in 1896, escaped in 1897; while Groups IV and X were spared in both years, as well as in 1895 and 1894. These two last groups lie on opposite sides of India, and contain, respectively, the European garrisons of Calcutta and Bombay, and the reason why they should escape is at

present not obvious. Twelve stations only were attacked in 1897, against twenty-five, three of them suffering only in 1897, and nine in both years, while some escaped that had been affected in 1896. Among stations, Lucknow,* Rangoon, Ranikhet, and Kasauli, had the greatest numbers of cases, Lucknow and Rangoon having been at the head of the list also in 1896. At Lucknow, Ranikhet, and Kasauli the outbreaks were compact, and were confined to two, or, at the most, three months ; while at Rangoon the disease did not finally cease till after the first eight months of the year. The average number of men constantly sick with influenza was 10, against 61 in 1896, and the average duration of a case 13 days, against 28. The returns deal, of course, only with those cases which were admitted into hospital, but there were mild cases not admitted. On page 69 is given a table showing the relation, year by year, of influenza to pneumonia, and of the influenza of the European troops to that of the native troops and to that of the prisoners. The admission ratio of the first was a little lower than that of the second, less than half that of the third.

Cholera.—General questions regarding the etiology, spread, and prevention of cholera, and the circumstances, so far as they are of importance, attending the most severe outbreaks of 1897, are discussed under Chief Diseases, page 94.

The amount and proportion of cholera were greater than in the previous year, but the ratios were somewhat lower than those of the decennium, as may be seen in the following table :—

Period.	Admissions.		Deaths.	
	Number.	Per 1,000 of strength.	Number.	Per 1,000 of strength.
1886–95	1,280	1·9	901	1·33
1896	70	1·0	63	·89
1897	117	1·7	80	1·17

The disease was at its maximum in September ; but in only three months of the year —January, March, and December—was there an absence of cases. Of the stations, Sitapur with 65 cases, or about 56 per cent. of the total for India, and Muttra with 9, suffered most. The regiments yielding the cases at these two stations respectively, were the 1st Battalion, Shropshire Light Infantry, and the 5th Lancers.

Small-pox.—The admission-rate from small-pox was a little less than a quarter, and the death-rate a little less than a half, that of the preceding year ; the former being reduced from 1·7 to 0·4, and the latter from 0·14 to 0·06. There were only 24 cases with 4 deaths, against 122 cases with 10 deaths. The admission-rates and death-rates were both below the decennial ratios of 1886-95. Not more than three cases occurred in any one station. In Burma Coast and Western Coast, as in the previous year, and in Indus Valley, Southern India, and the Hills, small-pox was absent.

Ague, Remittent Fever, Simple Continued Fever, Malta Fever.—Ague gave rise to over 25 per cent. of the admissions from all causes. The abundant and widely-distributed rainfall following on prolonged drought favoured the prevalence of malaria.

Period.	Intermittent Fever.		Remittent Fever.		Simple Continued Fever.	
	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.
1886–95	353	·18	9	·54	57	·04
1896	239	·10	14	·40	30	—
1897	395	·41	25	·60	43	·01

* The medical officer in charge at Lucknow is somewhat inclined to think that the diagnosis should have been Dengue rather than Influenza.

The ratios were above those for the decennium. In 1897 ague ratios were high in the ndus Valley, Central India, and Upper Sub-Himalayan, and low in Burma Coast, Burma Inland, the Hills, Southern India, and Western Coast; and that that is a usual state of things, as regards the first three and the last two, may be seen from the following :—

Period.	Ratio per 1,000 of Strength.												
	I.	II.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII*a*.	XII*b*.	
	Burma Coast and Bay Islands.	Burma Inland.	Bengal and Orissa.	Gangetic Plain and Chutia Nagpur.	Upper Sub-Himalayan.	North-Western Frontier, Indus Valley, and North-Western Rajputana.	South Eastern Rajputana, Central India, and Gujarat.	Deccan.	Western Coast.	Southern India.	Hill Stations.	Hill Convalescent Depôts and Sanitaria.	India.
1886–95...	194·5	531·2	381·8	216·9	465·5	632·4	496·9	228·0	164·3	119·0	291·0	320·4	352·9
1896 ...	105·3	157·1	204·9	183·4	248·7	523·5	376·1	265·1	75·8	80·3	163·9	178·8	239·0
1897 ...	47·4	132·6	383·9	246·7	422·6	761·8	584·2	333·3	182·2	139·4	128·1	158·7	394·7

The great fall of ague and influenza in Burma Coast was accompanied by a great rise in simple continued fever ; and the medical officer suspects, and probably with justice, that the change is due to difference of opinion among the medical officers in the matter of the diagnosis of those fevers. The most malarious month of 1897 was November, and the least malarious February. At Barrackpore and Neemuch malaria is said to be encouraged by the deficiency of the drainage. At Nowgong malarial fever was associated with a debilitated and scorbutic condition of the men. Irrigation is said to be increasing the dampness of the climate of Mooltan, and therefore malaria. The medical officer at Karachi points out that ague now appears in the returns to the exclusion of simple continued fever, whereas many cases of the latter used to be returned at that station. He notices also the frequency of melæna. At Hyderabad malaria was increased by the unusual extent of country flooded by the Indus. The medical officer at Quetta says :—

> The parasite seen in Quetta in cases contracted locally is the unpigmented quotidian variety, viz., small intracorpuscular unpigmented bodies, whereas in cases contracted in Sind crescents and spherical extracorpuscular pigmented bodies are of common occurrence thus showing a more malignant form of malarial infection in Sind.

The reports of the results of the prophylactic issue of quinine were, on the whole, favourable, though some medical officers were doubtful.

Both morbidity and mortality from remittent fever increased in 1897. The ratios from this disease were high in the Tochi and Malakand Field Forces, mortality being high in the former. The geographical group which showed the greatest increase was Burma Inland. The medical officer blames the water-supply, which comes from what "is not much better than a large marsh," and also the deficient drainage ; and ascribes the remittent fever to malaria, which was unusually prevalent. Remittent fever, like ague, in 1897 was most prevalent in November, and least prevalent in February. This distribution is not the same as in 1896. All the fatal cases were ascribed to malaria or "climate," and the *post mortem* appearances on the whole were in accordance with the diagnosis ; though in four cases there were some swelling of the lower Peyer's patches, in one case an ulcer on the ileo-cæcal valve, in one case small transverse ulcers with general peritonitis, in three cases a little lymph on the cerebrum, in one case small patches of pneumonia, and in one case pleuro-pneumonia with a localised inflammation of the liver suggestive of incipient abscess. In one case the enlarged spleen ruptured itself.

The rise in simple continued fever was greatest in Burma Coast, Bengal-Orissa, Central India, the Deccan, and Southern India, the stations with the highest ratios being Fort Allahabad, Benares, Thayetmyo, Pallavaram, and Mandalay. The medical officer at Mandalay was the only one to attempt an explanation, and that was that the men of the garrison were new to the country. The only fatal case returned as simple continued

fever died from hyperpyrexia, and the *post morten* examination showed a greatly enlarged spleen, unusually prominent Peyer's patches, signs of commencing inflammation at the bases of the lungs, and congestion of the kidneys. Possibly an examination of the splenic pulp, or of the contents of the gall-bladder, might have revealed the presence of the enteric bacillus. In fact, as in former years, some medical officers note that cases returned as simple continued fever may have been mild cases of enteric fever ; and they differ in practice as to where they draw the line between simple continued fever and enteric fever, as well as between simple continued fever and ague. The medical officer at Rangoon notes that what is called by one medical officer "influenza" may by another be designated "simple continued fever." As an aid to diagnosis Widal's test was used at Dagshai and Quetta and at the former cultivations were made from the spleen in some cases.

On page 23 of the report for 1896 (page 50 of the Parliamentary Report) was noticed the assertion that Malta fever has been shown to occur at Subathu. On this point the medical officer at Subathu in his report for 1897 says—

"It has lately been suggested at home that many of the cases described as "typhoid" in India, "and more especially in Subathu and neighbourhood, are in reality cases of Mediterranean or "undulant fever. It is not unreasonable to suppose that a man coming from a Mediterranean station, "or from some locality where undulant fever is endemic, and having absorbed the specific poison of "that disease, may have a recrudescence in India. But, so far as careful observation entitles me to "form an opinion, I am convinced that few, if any, such cases have occurred in Subathu during the "past year. Certain of the more dubious cases returned as "remittent" may possibly have partaken "of this nature ; but all the cases returned as "enteric" were very deliberately diagnosed ; each and "every one was clinically indistinguishable from "typhoid" as observed at home ; and in every fatal "case the pathological appearances were characteristic of that disease."

As a matter of fact, no cases of Malta fever were *returned* in India ; but the question whether the disease really *occurs* in India is well deserving of further and painstaking investigation. Good authorities are of opinion that the fevers of India require, and will obtain, greater differentiation.

Enteric Fever.—The reaction against the extreme opinion that enteric fever is exclusively a water-borne disease appears to have set in, and in England in 1897 the *rôle* of the soil in the nurture and dissemination of the enteric bacillus has been magnified. Water-carriage of enteric fever, according to Robertson of Sheffield, is, as all acknowledge, a very important subject, but, at the same time, he thinks that the amount of attention it has received has to a large extent put out of account the relatively much more important subject of dust- and filth-borne enteric fever. In his experience certainly over 80 per cent. of cases of enteric fever in town districts cannot be accounted for by water or milk-carriage of the infection, or by direct infection. As he estimates that about 10 per cent. of the cases of enteric fever are due to direct infection, but a small balance is left over for water-borne enteric fever. He looks upon the soil as the home of the bacillus, the winds as its usual, the waters as its occasional, carriers. To the immediate acceptance of these views two difficulties, perhaps not insuperable, give pause. In the first place, Dr. Robertson himself was never able to find the enteric bacillus in polluted soil, unless he had previously placed it there himself in the course of his experiments. But, according to many authorities, matters are in exactly the same case as regards water. In the second place, experiments such as those of Germano, referred to on page 24 of the report for 1896, and those of Neisser, go to show that the enteric bacillus cannot survive drying sufficient to make it portable by the air ; though those of Flügge somewhat modify that conclusion, and Fischer seems to be of opinion that the enteric bacillus can survive a good deal of drying. It must be remembered, too, that if the wind cannot transport undried enteric bacilli, flies can. The enteric bacillus is said to have been found in the dust of enteric fever barracks in France and Russia ; but in this case, as in that of water, some searchers are more easily satisfied than others. Thus, Childs says of the enteric bacillus : "This parasite has practically never been found in the surroundings of man, neither in air, nor soil, nor water, nor food, nor in the sewers or deposits of filth, which constantly receive countless hosts ; except in those cases where it has been implanted for the purposes of experiment, and in certain rare instances where it has been detected in connection with some typhoid outbreak." Dr. Robertson made some very interesting experiments on the behaviour of the enteric bacillus in fields in the open air, the result of which, in brief, was that the enteric bacillus left to itself perished in a comparatively short time, but if fed by the addition of organic matter to the soil, resisted the changes of season, and flourished as long as he had opportunity to observe. Similar results were obtained by Sidney Martin, working for the Local Government Board, and are referred to by Sir Richard

Thorne in a lecture emphasising the importance of the soil in the causation of enteric fever and some other diseases, the word soil being used in the part of the lecture that concerns enteric fever in its ordinary earthy meaning. Martin found that a porous, organically contaminated soil, containing about 35 per cent. by weight of moisture, and kept at a temperature of about 37° C., was the best adapted to the growth of the enteric bacillus. Childs postulates for the occurrence of enteric fever, firstly, the presence of the specific microbe in the soil ; secondly, a population susceptible or predisposed to infection ; thirdly, pollution of the soil, with certain conditions of porosity affected by temperature and moisture or the oscillations of the ground water. In connexion with the question of soil, Thorne, Robertson, and Caley refer to the fact that through a period of years, and notwithstanding a general change in the amount of enteric fever all over the country, the same parts of England remain maximum and minimum. The maximum parts are the northern counties of England and the south-western of Wales. Parsons connects this with the comparative backwardness of sanitation and the survival of the midden system in the north of England, while Robertson points out the need for further inquiry. There are some indications that certain parts of India are more constantly distinguished by high ratios of enteric fever among European soldiers than others ; but sufficient data have not yet been collected to justify a definite opinion. It has been noticed in England that where a part of the country usually comparatively free has been severely attacked, it takes a year or so to recover itself ; and this is held to indicate a gradual "healing of the soil" in the absence of opposing circumstances. On the other hand, Childs, the author of the phrase "healing of the soil" points out that where the contamination is continuous, drastic sanitary operations are a necessary preliminary to the healing of the soil. On the other hand, Poore shows that in China, where excreta are religiously collected and place on the fields, the mortality from enteric fever among British soldiers is low. According to Robertson, the largest number of organisms is not at the surface but at a depth of 12 to 24 inches below the surface ; and in an undisturbed soil the number of organisms rapidly diminishes at a depth of 3 to 4 feet from the surface, though faults and porous strata may allow them to be carried down to great depths. The enteric bacillus planted at a depth tends to grow upwards. The effect of sunlight is limited to those organisms actually on the surface. But the chief self-cleansing processes of the soil take place neither on the surface nor in its depths, but in its upper layers. "Burying excreta," says Poore, "as is sometimes done [*i.e.*, too deeply, and firmly covered in] is "like laying down port : the bacilli are not destroyed, and only require digging up to "spread infection." The researches of Germano have been referred to above. These have now been completed ; and, premising that Germano's argument is that an organism that cannot survive drying cannot be carried alive by the wind, his results, in brief, are :—The cholera spirillum, the plague bacillus, and the enteric bacillus cannot resist drying ; the diphtheria bacillus, the pneumococcus, and the streptococcus, can live some time dry ; the most resistant of all is the *meningococcus intracellularis*, and next to it the tubercle bacillus and the staphylococcus. The somewhat peculiar opinion of Paget is that the enteric bacillus exists in virgin soil, but in such a condition that it requires education before it can produce typical enteric fever ; and that the so-called typho-malarial fever is due to an uneducated bacillus.

On the whole the opinion of the day seems to be that the bulk of ordinary enteric fever is soil-derived, but sudden widespread outbreaks water-borne. When outbreaks occur simultaneously over a wide extent of country, they may be due to some combination of polluted soil and climatic conditions, with here and there incidental secondary contamination of the water, rather than to simultaneous accidental fouling of water-supplies. A specifically polluted soil is to the inhabitants of the place a constant threat of danger through the water-supply, as well as through the many other channels by which its particles can reach the interior of the body, while a non-specifically polluted soil is only one degree less dangerous, for it is a favourable nutrient medium prepared and ready for the enteric microbe whenever it shall arrive.

To those who say that climate is nothing, the parasite everything, it may suffice to point out that it takes two to make the disease, the host and the parasite ; that these two are engaged in a life and death struggle, that even a slight advantage or disadvantage on one side may decide the result ; and that the Indian climate is certainly not bracing to the European constitution. In the same way a native of India if transported to England is depressed by the cold, has his lungs irritated, and is much more apt to fall a victim to tubercle than in his own country. Many experienced medical officers are impressed by the occurrence of cases which seem to show that over-exertion in the heat renders a man an

easier victim, and that with respect to enteric fever liability too much exercise is more dangerous than too little.

Though the presence of the enteric bacillus has been but seldom reported in the intestine or gall-bladder of men not suffering or recovering from enteric fever, there are those who believe that it is often present, and would be more often found if looked for oftener and with adequate means. According to them, men very generally carry about in their bodies the enteric baccillus, which remains quietly waiting its opportunity. That a man escapes is due either to permanent insusceptibility or to temporary insusceptibility or to the absence of the bacillus. According to them again, a man may get enteric fever in one of two ways. Either some indiscretion of diet or exercise, or a lowering climatic influence, diminishes his power of resistance and enables the bacillus, hitherto resting peacefully in his body, to become an active invader of the same ; or while he is in a susceptible condition, bacilli from the stools of another case gain access to his body through water, food, &c.

Experiments on animals by Remlinger and by Chantemesse appear to their authors to have had more satisfactory results than those of previous observers.

Osler seems now to have adopted the opinion of Sanarelli, quoted on page 25 of the report for 1894, that enteric fever is no more primarily an intestinal than small-pox is primarily a cutaneous disease. On the other hand Sidney Martin is of the old opinion that the disease probably begins at the intestine and not at the blood.

Block on two occasions cultivated the enteric bacillus from a hypodermic-syringeful of the patient's blood, and after death the bacillus was found in the liver, spleen, kidneys, and in a piece of retained placenta—along with other microbes. Takaki and Werner succeeded in finding the bacillus in blood taken from the roseola.

Cases of enteric fever without intestinal lesions have been mentioned in former reports. Osler now divides cases of enteric fever as follows :—Firstly, ordinary cases with intestinal lesions ; secondly, septicæmic cases, general infection without special local manifestations, the diagnosis being made by means of Widal's reaction and by means of cultivations of the bacillus from the organs ; thirdly, cases with localisations other than intestinal,—pulmonary, splenic, renal, cerebro-spinal ; fourthly, cases of mixed infections. This division meets with the approval of the *Lancet* reviewer. Chiari and Kraus report a number of cases in which the presence of Widal's reaction during life caused the organs to be searched for the bacillus, though there were no intestinal lesions. In some the bacillus was found in the gall-bladder, mesenteric glands, spleen, kidneys, urine ; while in others, though no bacilli were found, the fluids of the body continued to give Widal's reaction *post-mortem*. Others also have reported cases. Their experience seems to indicate that " pure septicæmic enteric fever is relatively frequent." Durham, on the other hand, is of opinion that to the bacillus of Gaertner, and not to that of Eberth, belong the similar cases of " septicæmic enteric fever " which he had seen described as occurring in France, in which death occurred before typical typhoid lesions developed. Some of the observers who have brought forward the cases without intestinal lesions point out that if the bacillus is to be found at all in a body it will likely be found in the gall-bladder ; and that in the gall-bladder it may remain more or less inactive for long periods after health is re-established, during which at any moment it may be excreted into the intestine, and so perhaps make a healthy man a source of infection to others. The bacillus is even said to have been found in the gall-bladder in one case in which there was no history of previous enteric fever. Horton Smith reports that it was found in the fæces of convalescents 12 days after defervescence by Brieger, and 41 days after by Lazarus, and that he himself found it in urine 22 days after. It has also been found in abscesses years after.

Sterling reports that without the aid of Elsner's method he succeeded in demonstrating the enteric bacillus in fæces in only 16·4 per cent. of the cases, whereas by the use of Elsner's process he was successful in 60 per cent. ; but that, while a positive result is decisive, a negative is not so. He detected the bacillus in 60 per cent. of the patients, in 66 per cent. of the examinations made, in 44 per cent. of the examinations in the first week of the fever, and in 87 per cent. of the examinations in the second and third weeks. Others have characterised the method as good but requiring a long time ; while by at least three observers it has been unfavourably reported on. None of the newest methods seem to have won for themselves immediate general approval and adoption. In several volumes of this report the enormous difficulty of the diagnosis of the enteric bacillus, especially in water, has been emphasised ; and a similar opinion is expressed in the Army Medical

Department Report for 1895. Van de Velde, among others, states that he has never succeeded in finding the enteric bacillus in water. On the other hand, it is well known in India how frequently Mr. Hankin finds the bacillus, or something very like it, in water and elsewhere. Mr. Hankin, in his Annual Report for 1897 says,—

" The enteric microbe was searched for in 87 specimens of water, and detected in 29 instances. The " isolation of the enteric microbe is known to be a difficult matter, and as some doubt has been " expressed whether the enteric microbes and microbes suspicious of enteric that I have isolated from " water really deserve that name, I have submitted a dozen of these microbes, obtained from as many " different specimens of water, to Professor Pfeiffer of Berlin, the leading European authority on the " subject. He informs me that he has subjected these cultures to a minute examination, and that all, " or nearly all, are typical enteric in every respect."

Kister is one of the latest observers who report favourably on the use of Widal's test in the examination of suspected bacilli from water; and Hankin in some of his analytical reports mentions the finding of bacilli, which, besides presenting other characters of the enteric bacillus, reacted with Widal's serum. Durham divides the bacilli which cause the chief difficulty in diagnosis into three groups—the Gaertner group, the Eberth group, and the Escherich group; but these groups are not sharply defined one from another, and it is sometimes only by a majority of properties that a given microbe is assigned to one group rather than to another. Durham also asserts that the bacillus of Gaertner has been known to give Widal's reaction with enteric serum, and this appears to be accepted by Sidney Martin. Durham, in fact, considers that the bacillus of Gaertner causes a fever without intestinal lesions, which has been mistaken for enteric fever.

A case has been published of fever which ended fatally by perforation of the intestine, a virulent colon bacillus being found in the spleen. As usual a large number of diseases were attributed to the *bacillus coli*; but in some of the cases the infection may have been secondary, or may even have been *post-mortem*. It is believed to be possible that active infection by the enteric bacillus and the *bacillus coli* may be simultaneous, and experiment gives some countenance to the idea that the two may aid each other in their work of destruction.

The spread of enteric fever through the air around the patient is generally doubted; but Dr. Budd strongly maintained that such communication was not only possible but frequent, and Dr. Corfield believes that he was right. There are others who believe in the direct infectiousness of enteric fever, especially in the crowded dwellings of the poor; but it may be considered doubtful whether the disease would, even under such circumstances, be conveyed without the agency of dirty fingers and other uncleanlinesses.

The idea that flies convey infection is probably a very old one. Of late years many medical officers have referred to the matter in reports on outbreaks of enteric fever or cholera; and many of the cook-houses for British soldiers in India are protected with wire gauze for the very purpose of shielding food from the visits of flies, which may have come from latrines or other unclean resting-places. Among the neatest bacteriological investigations of the subject was one in which flies were allowed to alight upon a culture of *bacillus prodigiosus*, this bacillus being chosen because of the striking red colour its cultivations display, and then given opportunity to walk over the surface of sliced sterilised potato. The results were, as might have been expected, positive and conclusive. Various other experiments, also all with positive results, have been made with flies and other insects as to their power of conveying the enteric, cholera, cholera nostras, tubercle, and anthrax bacilli, and the staphylococcus. The microbes in an active condition were also found in the excrement deposited broadcast by the flies. Lately a report, couched in somewhat superlative terms, has been published in the *Lancet* to the effect that an American scientific commission appointed to examine into the causation of enteric fever in the military camps, had come to the conclusion that flies were the chief agents in the spread of the disease. Very interesting and important, though not bearing directly on enteric fever, are the investigations of Amedeo Berlese. His experiments prove conclusively the great part taken by insects, especially ants, and several kinds of fly, not only in the distribution (as was already known), but also in the preservation and multiplication of alcoholic ferments. Insects, far more than the atmospheric air, contribute to the dissemination of yeasts, which they convey rather internally than externally. There is, moreover, reason for believing that during the cold season some yeasts are chiefly preserved, and perhaps increased, within the organs of insects.

The most important recent researches on the presence of the enteric bacillus in the urine are those of Petruschky. He found, like others, that the excretion of enteric

bacilli in the urine is relatively rare, and begins so late in the course of the disease as to be useless for diagnostic purposes. But he also discovered that in many cases the excretion of bacilli may be so enormous that millions may be contained in one cubic centimetre of the urine ; and that this hyper-excretion may go on for weeks, and, what is obviously of great importance, may continue so long after the beginning of convalescence, as to constitute a real, though hitherto unsuspected, danger to others. He points out that such a case might cause a sudden great increase in the contamination of a water-supply ; and the importance of frequent examination of the water. He also gives the following account of an involuntary experiment on the human subject. During the absence of the sister who was nursing him, a delirious patient suffering from enteric fever urinated into a champagne bottle that was standing by his bedside. When the sister poured out the fluid into a glass to give to the patient, she was struck by its cloudy appearance, and tasted it to see if it was all right. Though she at once recognised what it was, and was seized with vomiting, yet in about 12 days she fell ill of enteric fever. Urine which contains these large quantities of bacilli is always cloudy. He has not succeeded in finding similar exaggerated excretions of bacilli in fæces.

Besides the importance of examining the sources of the water-supply and their surroundings, two points have lately been insisted on : the necessity of obtaining a local standard of water, the necessity of frequent examination and of not trusting to the negative evidence of a single sample. That the first is a convenience as well as necessity has been emphasised by Duclaux. Opinions differ as to the meaning of the presence of the colon bacillus in water, but all seem agreed that its presence in abundance always indicates danger, being due to pollution of the water by alvine discharges or sewage or fæcal dust. The colon bacillus isolated from water sometimes gives confusing seral reactions. The following is condensed from a leader in the *Lancet* on the report of Adams (chemical) and Washbourn (bacteriological) on the Farleigh water-supply of Maidstone :—

" It becomes essential to have an intimate knowledge of the composition of the pure water of the " district, before it is possible to form an accurate estimate as to the purity of any sample from " a source within the district. Except within narrow limits, there should be no departure whatever " from that standard. Departure from the standard signifies pollution. The nature of the pollution, " though of a harmless sort one day, may be changed for a dangerous sort another day. It may " be accepted almost as an axiom that any water which at all seasons and under varying conditions " remains unaltered for, say 12 months, may be looked upon as a permanently good water ; whilst " any water, from whatever source, which undergoes even slight changes as regards its mineral " and organic constituents in solution, must be recognised as a water which, though not actually " polluted, is always open to suspicion, from the fact that it is open to contamination, sometimes, of " course, of a specific nature. Even slight irregular variations are more important than the presence of " moderate but invariable quantities of certain substances which are sometimes supposed to indicate " by their presence a certain amount of contamination. . . . It is impossible to make an arbitrary " limit as to the number of bacteria which is to be taken as the standard of purity ; but Koch's " dictum may be accepted that water containing fewer than 100 bacteria in the cubic centimetre may " be considered a good water, provided they are the ordinary water-bacteria. The presence of one or " two coli bacteria in 100 c.c. of water is probably not a matter of much importance, although the " presence of a large number (such, for example, as the 60 colonies in the c.c. in one of the samples " examined) is a definite proof of contamination with animal excreta."

Reference is made on the next and following pages to the cases in which the enteric bacillus was found in water-supplies in India during 1897 ; and on the preceding page are given some important remarks of Mr. Hankin on the subject. Some careful work on filters has been done by Sims Woodhead and Cartwright Wood : many filters of different makes were tested, and their individual merits and faults clearly stated. But it must always be remembered that it is never wise to trust to filtration for safety, when the water is known to be contaminated : the way of wisdom is to see to the removal of the contamination at its source. Some striking statistics of the result of an improved water-supply in diminishing the morbidity and mortality from enteric fever have been published. It was found in the Agra laboratory that one way by which pure water could be contaminated was by the pathogenic microbe growing through the porous walls of the water-vessels into the contained water. This would seem to require confirmation, as it appears to be at variance with the results of Abba quoted on page 24 of the report for 1896. Poore has drawn attention to the dangerous dead-house practice of washing out the intestines of bodies of men dead of enteric fever and letting the intestinal contents and the water flow away into the drains without any attempt at disinfection. This point should be attended to in India, as the drains from dead-houses there are mostly simple surface-drains.

Under the ordinary conditions in which milk reaches and is kept by the consumer the enteric bacillus is capable of maintaining its existence in it, but without multiplication; in fact, it undergoes diminution, the rapidity of which depends on the number of rival microbes present. It can also exist in sterilised milk curdled by the *bacillus lactis*, and also in sour milk, so that it may possibly find its way into curd-cheese. It is said to survive for 48 hours in butter-milk. An epidemic in Hamburg, which chiefly affected women and children, was considered to be due to those properties of the bacillus. In bad and dangerous milk a bacillus which is either the colon bacillus or a near relation to it has been found.

The general opinion among those best qualified to judge is, at present, that the only possible way in which sewer gas and evil-smelling air can contribute to the causation of enteric fever is by lowering the general health and resisting power of men.

Heat remains the best disinfectant agent for the prevention of the disease—cooking of all food, boiling of water and milk, cremation of stools; and these measures have been practised to a considerable extent in India. All authorities seem agreed that pathological stools should be burned, and certainly in times of epidemics. But as it is not always possible to know that a stool is pathological and pathogenic, and as the burning of all night-soil is out of the question, the greatest attention should be paid to the proper disposal of the dejecta by superficial burial. Those concerned should lay to heart the words of Poore, quoted in the present paragraph under the heading "Soil," and also the following of the same author:—

"In order to prevent contamination of the water, it is best to burn the stools. But in the country "it would be best to put the excreta near the top of a recently-tilled humus. Merely digging a "trench, filling it with excreta, and covering it firmly with soil simply preserves the fæces, and "does not lead to their disintegration."

At hill stations also all stools known to be those of enteric fever should be destroyed. For the burial of the rest of the night-soil, which will always contain some dangerous stools, there is difficulty in getting sufficient land on the hill-sides; and the best plan is to convey the night-soil in wire-tramways down the hillside as far as may be thought desirable, or till a suitable trenching ground is reached. This system is working well at Murree, Gharial, Kuldunnah, and Lower Topa.

It may be of interest to record that P. C. Smith states that the enteric fever death-rate in London, which was in the decennium 1871-80 240 per million, fell to 190 in the decennium 1881-90, to 140 in 1895, and to 127 in 1896.

As usual many medical officers point out the influence of youth and of recent arrival in India; and some call attention to the increase of enteric fever subsequent to the arrival in a station of a new regiment, or of fresh drafts from England. The medical officer at Ahmednagar goes so far as to say that newcomers to that station are as such more liable to the disease, even though it be not their first term of residence there. Three men appear to have already contracted the infection before they landed in India. In 1897, as in former years, some cases were held to have originated *en route* from Bombay to inland stations, and the medical officer of Mhow calls for more stringent measures to protect fresh arrivals at Bombay, at Deolali, at the rest-camps, and while in the train. Again, medical officers frequently noted, especially in the case of hill stations, that the disease must have been contracted before arrival, either from impurities encountered on the march, or from a cause existing in the previous station, so that the station where the disease was treated was not always the station in which it was contracted. For example, eleven of the cases treated at Peshawar are said to have originated on field service. Some patients acknowledged having drunk foul or doubtful water in native villages, by the roadside, when out shooting, when bathing in a dirty stream, in the bazar, or from a forbidden source in cantonment. At Jhansi, Bangalore, Deesa, Subathu, and Amritsar it was noticed that men employed away from barracks, as military telegraph signallers, or policemen, or in practice and exercise camps, or at training and musketry, were liable to attack, whether from fatigue and exposure, or from having had opportunity to drink unclean water. While in some cases heat and fatigue were held to have been predisposing influences, in others illness was dated from a chill due to a wetting, or from a chill following overheating. The medical officer at Mhow considered that insufficient clothing had rendered a certain body of men more vulnerable. The water-supply was considered liable to contamination at Umballa, Dagshai, Subathu, Poonamallee, Mandalay, Ahmednagar, Mhow, Nasirabad, Hyderabad, and Sitabaldi; while in Fort Lahore, examination having thrown suspicion upon the well-water, recourse was had to a fresh source of supply.

Apparently, Calcutta, Attock, Madras, Bangalore, Wellington, Ramandrug, Rangoon, Thayetmyo, Purandhur, Nasirabad, and Taragarh are still exposed to the danger involved in a double water-supply ; and the medical officer of Nasirabad mentions that men had confessed to having drunk of the water reserved for washing and gardening, and notified by sign-boards as "Not for drinking," a water in which the presence of the enteric bacillus had several times been reported. Besides this, in the drinking-water of Lucknow, Fatehgarh, Meerut, Muttra, Agra, Subathu, Meean Meer, Amritsar, Cherat, Mhow, and Deesa, the bacillus, or a near relation of it, was found, mostly, or in every case, by Mr. Hankin. Two medical officers report that the same bacteriologist discovered the enteric bacillus in specimens of water that had been boiled and passed through a Pasteur filter. Mr. Hankin found the bacillus in milk from Fatehgarh and Dagshai. On the other hand, the result of the examination of water from Sitapur, Ranikhet, Chakrata, Jhansi, Dagshai, Solon, and Ahmednagar, was negative. At Quetta the arrangements for the supply of water to the kitchens and to the soda-water factories was considered such as to risk contamination of the water, and the *bacillus coli* is said to have been found in a specimen of soda water. In the beginning of 1898 Surgeon-Major Davies, on special duty, found a bacillus of the colon group in the water of the Mhow supply. Where *pakhals* and *mussacks* continue to be used, it appears, at least on paper, that systematic efforts are made to secure their constant disinfection, the most difficult cases being those where the use of leather vessels coincides with a double water-supply, and necessitates the provision of two sets of *mussacks* and *pakhals*. In some cases it appears that dislike of boiled water, or of water treated with permanganate of potash, was the cause of men resorting to forbidden sources, and anyone with a taste for water must sympathise with these men. The combined result of six stations was that 65 cases occurred among total abstainers, and 121 in non-abstainers, or 35 and 65 per cent. respectively. But, as their average annual strengths cannot be obtained, no conclusion can be drawn as to the relative liability of those two classes. An outbreak in Umballa was attributed to water drawn by a *bhisti*, to save himself trouble, from a well close to some old filth pits. At Indore a patient stated that he had drunk a quantity of soda water in a brothel about a week before the onset of his illness ; at Hyderabad a soldier had drunk lemonade in the bazar ten days before admission ; while at Chakrata a man who contracted the disease had drunk out of the bottle of a comrade in hospital suffering from enteric fever, the supposition being that the latter had contaminated his bottle in using it. An outbreak at Cherat was traced to the adulteration of milk with the water of a dirty tank, this water containing the enteric bacillus. The butter and milk were believed by a committee to have originated the first outbreak of the year at Mhow ; and, though doubts have been thrown upon the validity of this conclusion, it was found that the dairy arrangements were very defective. As usual, some medical officers point to the comparative immunity of women and children as an argument against the probability of the disease having been carried by the water or milk supplies, or to the scanty numbers and sporadic distribution of cases as an argument against it having been water-borne. The enteric fever of some stations was described as not epidemic but endemic, with regular spring and autumn exacerbations. The medical officers of three or four stations point out that all the attention lavished on the disinfection of the water has made little difference in the amount of enteric fever, and draw the conclusion that enteric fever is mostly contracted in the bazars, away from the barracks with their sanitary arrangements. Most medical officers are of opinion that much enteric fever is contracted in the bazars, and especially in the brothels ; and in support the medical officer of Fort Allahabad notes that eight out of nine cases occurred in the persons of bachelors, one of them having primary syphilis when admitted for the fever ; while, on the other hand, it is said by the medical officer of Nasirabad that no cases have been admitted from the married quarters for some years. None of the reports for 1897 mention the effect on the amount of enteric fever of placing the bazar out of bounds, though there are nearly a dozen references to the effects of this measure upon the statistics of venereal disease. The danger from the careless and dirty habits of natives allowed to be about barracks, and especially of native cooks, is insisted on by several medical officers. Two of them suggest that the men should be made to cook their own food, and this reform has actually been carried out in the case of Subathu. In some stations elaborate rules have been introduced to secure cleanliness in the kitchens, and measures have been taken to exclude flies. An outbreak of enteric fever in the hospital at Jhansi was attributed to the surreptitious introduction from outside of bazar-made sweetmeats and butter. At Dagshai the bread was freed from suspicion by examination. The medical officer at Nasirabad thinks there may be something in the fact that enteric fever is most common when there is most dust blowing about. It was discovered by the medical officer at

Campbellpur that the clothing of enteric patients admitted to hospital was stored without being washed, and, in the event of the patient's death, was sold without having been disinfected. At Dagshai it was noticed, as in some other years, that tonsillitis and sore-throat were prevalent at the same time as enteric fever. Of Bernardmyo, which was first occupied in 1888, it is said that there is no record of the occurrence there of enteric fever; and Darjeeling and Colaba are reported as comparatively immune. The reasons given for immunity in the case of Roorkee were a small garrison and no drafts arriving; in the case of Dagshai military prison, the not allowing any natives inside; in the case of Murree, a good and abundant water supply and careful sanitary attention; in the case of Colaba, the fact that the water-supply is at no point liable to contamination. Again, the reasons given for a diminution of the disease were, at Shahjahanpur, keeping natives away from the barracks; at Ranikhet the great precautions taken to secure cleanliness of water and milk; and at Dalhousie the sanitary measures of recent years. Among the measures considered to have been successful in staying an outbreak were removal from the neighbourhood of the unclean water (Umballa); boiling and permanganating the water, and inoculation of the supply with *micrococcus Ghadiallii* (Meean Meer); permanganating the water (Kamptee). The presence of the *micrococcus Ghadiallii* in the milk used by a regiment at Dagshai did not, however, apparently prevent that corps from suffering severely from enteric fever. That non-commissioned officers at Umballa suffered little was considered possibly due to the fact that only mineral waters were consumed at their messes. Some regiments and batteries have made very complete arrangements for securing cleanliness in their aërated water factories and in their dairies, but, as a rule, the existence of weak points is reported. For the purification of water alum appears to be used only in about half-a-dozen stations, whereas boiling and permanganating with more or less thoroughness seem to be general. The Larymore boiler, as made and used by the jail department of Bengal, is being introduced at some stations, and has so far met with approval. Incineration of enteric stools is reported from Dagshai, Subathu, Jutogh, Mooltan, and Gharial; but it seems that those are not by any means the only stations in which such a procedure is carried out. At Chakrata urine, fæces, &c., were boiled. Finally, on account of the difficulty of maintaining biological cleanliness in all things in India, some medical officers, amongst whom is he of Chakrata, desire the prophylactic inoculation of all men coming to the country. Out of the 2,214 cases of enteric fever which occurred throughout the army of India in 1897, 49 are noticed as having declared themselves among patients in hospital or among attendants. Out of these, 11 were in hospital for early venereal disease, 19 were in hospital for late venereal or other diseases, and 19 were attendants on enteric fever cases. The number of attacked attendants returned is much greater than usual. A second attack of enteric fever was the lot of a man at Meerut, whose first attack had been at Cairo. In four cases at Mhow and in one case each at Pachmarhi, Meerut, Sialkot, St. Thomas' Mount, Bangalore, Belgam and Rangoon an association, contemporaneous or successive, of enteric fever with dysentery was observed. A case each of enteric fever at Sitapur, Sialkot, Belgam, and Quetta was complicated with abscess of the liver; while in two cases of abscess of the liver, which occurred, respectively, at Lucknow and at Secunderabad, the origin of the abscesses was stated to have been the intestinal ulceration of enteric fever.

Medical officers have reported on the outbreaks in the case of which the drinking water was suspected, or was said to contain the enteric bacillus; of the measures considered to have been effectual in preventing or checking the disease; and especially of the results obtained by boiling the drinking water, or by adding to it potassium permanganate or other chemicals. Instances are given where the purification of the water was not properly carried out, or was even so carelessly managed as to be worse than useless—to be mischievous. But the disappointing figures in the following table seem to show either that the measures in question were more generally mismanaged than would appear from the reports, or that they are of no use, or that the main sources of the infection were outside the regular water-supply. If the actual increase of enteric fever was not due to contamination of water from unintelligent handling after it had been drawn for use, it may conceivably have been due to the concentration of sanitary attention on the water-supply to the comparative neglect of those other sources of infection. It seems hardly likely, however, that good measures put in force simultaneously throughout the British cantonments of India, should have been everywhere mismanaged, and should in two years have produced absolutely no good effect. The alternatives, therefore, seem to be either that the measures were not of a kind to do good, or that, being good, they were not applied to the cause of the evil. The same suspicion which has already arisen in England, arises in India, that, while sudden extensive epidemics are due to contamination of the water-supply,

the mass of ordinary cases that occur singly or in small groups must have some other origin, or, more probably, origins. There is uncleanliness of soil, of cook-houses, of latrines, and there are the many uncleanlinesses of the native bazar.

Commands.	Year.	Enteric Fever.		
		Admissions.	Ratio per 1,000 of strength.	Difference.
Bengal	1896	679	30·2	+ 8·9
	1897	786	39·1	
Punjab	1896	488	25·9	+ 16·2
	1897	724	42·1	
Madras	1896	227	16·8	+ 2·4
	1897	237	19·2	
Bombay	1896	401	25·5	— 5·1
	1897	303	20·4	
India	1896	1,795	25·5	+ 6·9
	1897	2,214	32·4	

No explanation can be offered as to the exceptional experience of the Bombay Command. The chief reductions in the command were at Quetta, Kirkee, Deolali; but the "medical transactions" of those stations throw no light on the point.

Enteric Fever in 1897.—There was a considerable increase of both morbidity and mortality from enteric fever in 1897. The admission ratio rose from 25·5 to 32·4, and the death ratio from 6·31 to 9·01, a difference of 6·9 and 2·70 per 1,000, respectively. There were 2,214 admissions and 616 deaths, against 1,795 and 445 in 1896. The average number of men constantly sick from enteric fever was 297, and the average duration of a case was 53 days. The total loss of service due to the disease was about 108,350 days. At Dagshai and Quetta Widal's test was employed as a means of diagnosis.

Fever Mortality.—The following table shows an increase in total fever mortality, which may with some reason be ascribed to the greater youthfulness and less average length of service of the soldiers of to-day :—

—	1870–79.			1881–90.†			1896.			1897.		
	Enteric fever.	Other fevers.*	Total of both.	Enteric fever.	Other fevers.*	Total of both.	Enteric fever.	Other fevers.*	Total of both.	Enteric fever.	Other fevers.*	Total of both.
Army of India	2·03	1·42	3·45	3·79	·70	4·49	6·31	·50	6·81	9·01	1·02	10·03

* Intermittent, remittent, and simple continued fevers.

† Excluding troops on active service in Burma during 1885 to 1887.

As compared with the decennia, 1896 exhibits a more usual state of matters than 1897,—an increase of mortality from enteric fever accompanied by a decrease in mortality from the other fevers, which condition of things is usually, and probably with right, ascribed partly to increased susceptibility to enteric fever on the part of the Army from

youth and recent arrival, and partly to the increasing frequency with which the diagnosis of enteric fever has been made. The year 1897 had a high death-rate from "other fevers," because it was a very malarious year. But the statistics of the last twelve years lend no support to the supposition that prevalence of and mortality from Indian enteric fever vary directly as the malariousness of the year.

The following table shows enteric fever in the geographical groups in the decennium 1886-95 and in the last two years :—

Admissions per 1,000.

Period.	Burma Coast and Bay Islands.	Burma Inland.	Bengal and Orissa.	Gangetic Plain and Chutia Nagpur.	Upper Sub-Himalayan.	North-Western Frontier Indus Valley, and North-Western Rajputana.	South-Eastern Rajputana, Central India, and Gujarat.	Deccan.	Western Coast.	Southern India.	Hill Stations.	Hill Convalescent Depôts and Sanitaria.
	I.	II.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII*a*.	XII*b*.
1886–95 ...	5·7	5·5	7·7	27·7	25·4	15·6	23·9	17·0	5·8	12·1	25·1	13·9
1896	13·0	4·5	18·3	40·0	19·8	23·8	30·4	23·1	17·4	16·0	47·2	10·3
1897	0·8	1·1	11·0	36·9	33·5	22·3	63·7	24·3	10·2	26·8	49·7	14·9

It shows that Groups V, VI, VIII, and XII*a* especially, are apt to have high ratios of admission from enteric fever, and Groups II and X, and, to a less extent, I and IV, low ratios. It also shows at a glance how the groups compare with each other in 1897, and how 1897 compares with 1896 or with the decennium. Group VIII had the highest ratio of 1897, and Group XII*a* the next highest, and in the same two groups also, but in the reverse order, the percentage of enteric fever in total admissions was greatest. The table also shows that, whereas in nine groups the ratios of both 1896 and 1897 were higher than the corresponding ratios of the decennium, only in Burma Inland were the ratios of both years lower than the decennial ratios.

As regards enteric fever in stations the following shows those garrisons which had an average strength of over 1,000 in 1897, with the decennial ratios for reference :—

Stations.	1897.		Decennium, 1886–95.	
	Admission-rate.	Death-rate.	Admission-rate.	Death-rate.
Agra	166·4	45·04	24·0	7·66

Fort William	—	—	4·3	2·13
Aden	—	—	3·5	1·81

* Including Fort Allahabad.
† Eight Years.

The high position occupied by the decennial admission ratios of Bareilly and Lucknow will be observed, and the low position of the ratios of Aden, Calcutta, Bombay, and Rangoon.

In regiments the admission and death rates were highest in the cavalry; there was no enteric fever among the engineers, and, next to them, the artillery suffered least. The regiments which had an admission rate over 100 per 1,000 and a death-rate over 40 per 1,000 were the 1st Battalion, North Staffordshire, at Umballa, and the 2nd Battalion, York and Lancaster, at Agra. The former arrived from Egypt on the 1st November, 1897, and the latter from Mauritius and South Africa on the 21st February 1897. In the report for 1896 it is mentioned that one of the regiments that suffered most in that year had arrived during the year from Mauritius. In 1897 the North Staffordshire had 51 cases and 8 deaths, the York and Lancaster 165 cases and 45 deaths. The 1st Battalion, Royal West Surrey, and the 1st Battalion, East Kent, had also admission ratios over 100 per mille, and five other regiments admission ratios over 50 per mille. All but one of these seven regiments received over 100 men from England during the year.

With regard to the relation of mortality from enteric fever to age and length of residence in India, the general results confirm those of former years. The ratio of mortality from enteric fever per 1,000 of strength was greatest in the age-period 20—25, and the relative liability of the same period was 46 per cent. In the same age-period the total number of deaths from enteric fever was 417, and out of a hundred deaths from all causes 56 were from enteric fever. Lastly, out of the total number that died at all ages from enteric fever 76 per cent. were between 20 and 25 years of age. Again, the ratio of mortality from enteric fever per 1,000 of strength was highest in the first year of residence, and the liability in the same year was 36 per cent. In the first year the total number of deaths from enteric fever was 215, and 64 out of every hundred deaths from all causes were from enteric fever. Lastly, out of the total number that died at all periods of residence from enteric fever, 39 per cent. were in the first year of Indian residence.

The age period 20—25 included 52 per cent. of the total strength of the Army, and in the same period the liability to fall sick of enteric fever was greatest, 44 per cent. In the succeeding periods the liability rapidly and gradually declined. Again, 19 per cent. of the men of the Army were of less than one year's service in India, and it was among the men of this percentage that the liability to contract enteric fever was greatest, the liability thereafter markedly declining. Since arrivals have increased, and since the percentage in the Army of men under 25 years of age and of men with less than 5 years' Indian residence has been gradually mounting, the admission ratio from enteric fever has also been rising. The greater has become the supply of susceptible material, the more the disease has prevailed.

In the period 1886–95 as a whole the chief enteric fever season, though the disease occurred in all months, was the six months April—September, with one maximum in May and another in August:—

Year.*	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.	Ratio per 1,000.
1886–95†	518	418	689	1,427	1,795	1,365	1,441	1,718	1,400	923	745	879	13,318	19·6
1897† ...	86	79	147	313	223	168	179	238	232	131	207	211	2,214	32·4

* The warning given in the previous report as to the months not being calendar months applies to this report also.
† Including men on Field Service.

In 1897 the greatest prevalence of enteric fever was in April and May, and again in August and September; of simple continued fever in June and July; of remittent fever in November, September, and October. Of the larger groups Southern India had its enteric fever maxima in February and July, the Deccan in March and September, the Indus Valley in March and November, the Hills in April and July, Central India in April and August, Gangetic Plain and Upper Sub-Himalayan in May and December.

Plague.—In the European army of India there occurred only 5 cases of plague, and none of them proved fatal:

	Admissions.
Bombay (Colaba)	3
Poona	1
Purandhar	1
	5

The medical officer at Colaba says that the disease having been prevalent in the city of Bombay since September 1896, and a few cases having occurred within the European lines at Colaba among native servants and employés during the months of December 1896 and January 1897, the first case was admitted to the station hospital from the 3rd Company, Eastern Division, Royal Artillery, in Fort Mahaluxmi on the 31st January 1897, the second from the 2nd Battalion, Royal Dublin Fusiliers, on the 6th March, and the third from the same regiment on the 7th March. In all three cases the diagnosis was made in consultation; and the two last cases were seen by Dr. Yersin, who concurred in the diagnosis. The man found to have plague at Poona on the 29th September 1897 was a Bombardier, Royal Artillery, employed as a clerk in the District Staff Office, and living in the *sadar bazar*. The case at Purandhar occurred (date not given) in the person of a convalescent soldier sent up from Kamptee for climatic debility; and the man, says the medical officer, probably contracted the disease on his way up.

Respiratory Diseases caused less sickness and mortality than in the preceding year.

Of the commands, the Punjab had, as usual, the highest death-rate. As to groups, if the Convalescent Depôts be excluded, the greatest prevalence was, as usual, in the Indus Valley. No explanation is given of the large amount of bronchial affections at Calcutta, Mandalay and some other stations; at Ahmedabad and Bellary the cases were mild, and were ascribed to chills. Of the field forces, that of Tirah was the one which suffered most from respiratory disease, especially the non-pneumonic forms.

Possibly in connexion with the diminution of influenza, the admission and death-rates from pneumonia fell. Of the commands, the Punjab had the highest death-rate, as usual. The Indus Valley was, as usual, the group in which pneumonia was most prevalent; but in 1897 the ratio of the Convalescent Depôts was as high as that of the Indus Valley, and that of Upper Sub-Himalayan came only third, instead of, as usual, second. Peshawar had the highest ratio in the Indus Valley, and the medical officer states that malaria played an important part in the causation of the disease. The six deaths at Peshawar was the maximum at any one station; and medical officers do not appear to have felt called upon to dwell upon the causation in their reports. The disease was more evenly distributed throughout the months of the year than in 1896, the maximum being suddenly reached in the two most malarious months, November and December, when cold weather was establishing itself, and when malaria in 1897 was prevalent. These facts are evidently connected with the peculiar weather of the year, which has already been described. Pneumonia was most prevalent in the Tirah Force, the field forces being looked at alone, next in the Malakand Force; while there was no mortality from it in the Tochi and Mohmund Forces, and no cases of it at all in the Kohat-Kurram Force.

The number of European soldiers constantly sick from pneumonia was nearly 18, against 35 in 1896, and the average duration of a case about 31 days, against 35.

Dysentery and Diarrhœa.—The admission and death-rates from dysentery and diarrhœa rose very much. This is presumably due partly to the abundant monsoon rainfall following on a drought, and partly to the exposure and hardship to which the portion of the army on field service was exposed:

Period.	Dysentery.		Diarrhœa.	
	Admissions per 1,000	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.
1886–95	30	·73	32	·06
1896	26	·67	20	·01
1897	46	2·53	33	·23

The reason why the India ratio exceeds that of any of the commands is that "India" includes the field forces. Dysentery was most prevalent in the Madras Command and in the Bengal-Orissa and Southern India groups. The same command and groups had the highest percentages of dysentery in total cases, as may be seen in the Tables on pages 42 and 44. It is usual for Bengal-Orissa to have a high dysentery ratio. Dysentery was most prevalent in the period August–November, inclusive, the maximum month being November, and the minimum January. Of stations Secunderabad, Peshawar, and Rawalpindi had the most cases ; and Barrackpore and St. Thomas' Mount had the highest ratios for stations, and the Tochi by far the highest ratio for field forces.

The exact relation of the *amœba coli* to dysentery is still a matter of dispute and of doubt, which will probably only be cleared up when a successful method of cultivating the *amœba* has been discovered. Powell in Assam states that he has frequently demonstrated the *amœba coli* in dysenteric stools.

Hepatitis.—While the admission rate from hepatitis (including abscess of the liver) fell from 23 to 20 per 1,000 the death-rate rose from 1·25 to 1·32.

Venereal Disease.—From venereal disease the admission rate for India was 485·7, against 511·6 in the previous year and 522·3 in 1895. In other words, in 1897 for every 1,000 men there were nearly 26 fewer admissions to hospital for venereal disease than in 1896. The reduction appears to have been connected with the employment of a large number of men on field service in the second half of the year, as the number of venereal admissions was much lower from July to December than from January to June. In 1897 there were 2,991·59 (against 3,162·43) men constantly sick in hospital from venereal disease, equivalent to about three regiments. Excluding from the calculation men on field service, the average stay of a case of venereal disease in hospital was 33·32 days (against 32·10 in 1896, and 31·49 in 1895) ; and the total loss of service was about 1,091,930 days (against 1,157,449 in 1896, and 1,155,167 in 1895). There were 23 deaths, 0·34 per 1,000 of strength,* and 662 invalidings, 9·68 per 1,000, *directly* due to venereal disease, against, in 1896, 14, or 0·20 per 1,000 and 479, or 6·80 per 1,000.

The ratio of venereal disease to strength increased in 57 stations and decreased in 47. The highest ratios (over 900 per 1,000) were at Shahjahanpur, Chakrata, Saugor, and Ahmedabad. The greatest increases of ratio (increases of more than 150 per 1,000) were at Benares, Allahabad, Sitapur, Fatehgarh, and Chakrata in the Bengal Command ; Attock, Solon, Ghora Dhaka, and Cherat in the Punjab command ; Cannanore (strength under 100), Ramandrug (strength under 100), Poonamallee, and "on the march" in the Madras Command ; Kamptee in the Bombay Command.

A comparison of the commands shows that there was a decrease in Bombay only, a decrease greater than the increase of the other commands put together. The smallest increase was in the Punjab. As in the two years preceding, Bengal had the highest ratio, and the Punjab the lowest.

In 49 stations, against 46, the admission rate for secondary syphilis was over 100 per 1,000 of strength, the highest ratios being those of Poonamallee (as in 1896 and 1895), Taragarh (as in 1896 : strength under 100), Chakrata, Ramandrug (strength under 100), and Belgam ; and in 21 other stations, against 22, it was over 75 per 1,000.

For India the ratio of primary syphilis *plus* soft chancre diminished by 24·7, and the ratio of gonorrhœa by 5·3, while the ratio of secondary syphilis increased by 4·2 ; the net result being a decrease in total venereal disease, as already mentioned. While the secondary syphilis ratio of 1897 was greater than that of 1896 by 4·2, that of 1896 had been greater than that of 1895 by 12·8. In 1897 the Bengal Command had the highest ratio for primary syphilis *plus* soft chancre, and for gonorrhœa ; the Madras Command, as usual, the highest ratio for secondary syphilis. In the Bengal Command the Rohilkhand District had the highest ratio for each form of venereal disease ; while in the Madras Command the Belgam District had the highest ratios for syphilis and for secondary syphilis.

More or less explanation of the prevalence of venereal disease, or of its increase or decrease, is attempted by some medical officers. With regard to the result of placing bazar and city out of bounds, the medical officers of Meean Meer, Calicut, Belgam, Poona, Colaba, Kurrachee, and Hyderabad, speak favourably ; those of Subathu, Campbellpur, and Kirkee, unfavourably ; while with regard to Satara the result is not mentioned.

---

* Including men on field service.

Some medical officers consider that venereal disease and ague vary inversely to each other, ague diminishing virility.

The influence of the famine in increasing the number of prostitutes is noticed. At Deesa total abstainers were found to suffer more than others.

Sanitaria especially, but also other stations, returned cases which were really contracted before arrival.

The medical officers of Lucknow and Kirkee considered it probable that the cases returned as non-venereal buboes were mostly of venereal origin, though proof was wanting. The remarks of the medical officer at Calcutta on non-venereal buboes are to the same effect as those quoted in paragraph 30 of the report for 1896.

The subject of intramuscular injections of mercury is noticed in many reports, as well as continued peroral treatment in barracks, as a means of obtaining more thorough cures without losing the services of the men ; and the medical officer of Mhow points out the effect of this plan in reducing the number constantly sick in hospital, as well as the average duration of a case in hospital.

Statistics show clearly how the arrival year by year, especially since 1878, of fresh batches of young unmarried men under the short service system has been accompanied by an increase of venereal disease.

On the next page particulars are given regarding invaliding for venereal disease in relation to age and length of service.

The following table shows the admission rate for venereal disease as far back as the records for India as a whole permit. The heading " primary syphilis " includes the local sore throughout :—

Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Disease.	Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Disease.
1872	61·2	22·4	179·0	1885	122·1	28·7	342·7*
1873	53·4	20·4	166·7	1886	157·9	33·3	389·5*
1874	68·3	25·2	192·7	1887	142·1	29·4	361·2*
1875	67·1	25·1	205·1	1888	142·1	32·4	370·6
1876	59·8	23·9	189·9	1889	225·1	51·2	481·5
1877	65·2	22·1	208·5	1890	220·7	66·3	503·5
1878	95·3	22·0	271·3	1891	159·2	60·0	400·7
1879	79·2	24·5	234·8	1892	161·1	57·8	409·9
1880	87·9	23·1	249·7	1893	213·6	61·6	466·0
1881	92·0	23·1	260·5	1894	248·1	74·6	511·4
1882	87·6	23·2	265·2	1895	239·0	84·9	522·3
1883	87·2	23·5	270·3	1896	226·4	97·7	511·6
1884	90·2	24·4	293·9	1897	201·7	101·9	485·7

* Including troops on active service in Burma.

The figures in the above table show a more or less continuous rise, especially since the end of 1884 ; and though there was a fall in the general ratios in 1896 and 1897, the rise in secondary syphilis continued uninterrupted, the ratio of 1897 being the highest on record.

Invaliding.—In the whole army of India 2,258 men were invalided, or 33·01 per 1,000 of strength, against 1,966 and 27·89 in the preceding year, the increase being partly due to the larger number of men invalided for secondary syphilis. The ratio for the decennium 1886–1895 was 24·34. The proportion of invalids to strength was lowest in the Punjab command, and highest in the Madras command.

—	1893.	1894.	1895.	1896.	1897.
India	39	39	33	39	34

Thirty-four per cent. of the total number invalided were discharged as unfit for further service. As shown above this percentage was somewhat, though not unprecedentedly,

low. It should be mentioned, however, that the question in the case of each soldier as to whether the disability necessitates discharge is revised in England by a medical board ; so that the Indian figures do not show the real final disposal of invalids.

The following shows the diseases which accounted for invaliding ratios of not less than 1 per 1,000 of strength :—

Invaliding Ratios per 1,000 of Strength.	—
Syphilis and gonorrhœa	9·65
Debility	2·62
Malarial fevers	2·41
Tubercle of the lungs	1·94
Valvular disease of the heart	1·30
Dysentery	1·17
Rheumatism	1·11
Disordered action of the heart	1·10

The ratio of invaliding from mental diseases rose from 1·05 per 1,000 in 1896 to 1·39 in 1897, and was above the decennial ratio (1·19). There were 50 cases of melancholia, 35 of dementia, 15 of mania, and 14 of other forms of insanity.

The percentage of men who were invalided while under 25 years of age to the whole number invalided was 63, against 62 in 1896. The percentage of men under 25 in the strength of the army was 55, against 56.

Of the total number of men invalided, 32 per cent. were of less than two years' service, and 85 per cent. were of less than five years' service. With this is to be considered the fact that 84 per cent. of all the men in the strength of the army were of less than five years' service.

With regard to individual diseases the highest invaliding ratio per 1,000 of strength from venereal disease was in the age-period 20—25, and the relative liability for that period was 40 per cent. ; the actual number invalided for veneral disease in the same age-period was 426 ; of 100 invalided in the same age-period 31 were due to venereal disease, a proportion the same as in the next age-period ; and of the total invalided for venereal disease at all ages 64 per cent. were in that same age-period. The residence-period 2—5 years, and especially the second half of the period, had the largest proportion of invaliding for venereal disease, whereas in 1896 it was more particularly the first-half of the period 1—3 years which was so distinguished.

Statistics of officers.

The vital statistics of officers shows that the death-rate for the British Army was 23·04, and that for the Indian Army 18·92, both higher than in the preceding year, because of the fighting that had to be done in 1897. The number of deaths from enteric fever was greater than in 1896 among both British and Indian officers. Enteric fever caused, as usual, more deaths among the British than among the Indian officers, apparently because Indian officers have to serve first with British regiments, and it is known that youthful and newly-arrived men are more liable to take the disease than others.

The invaliding and death-rates were higher than for men, the admission-rates lower. The admission-rates from ague and venereal disease, and the death-rates from enteric fever and hepatic abscess, were lower than among men. The chief causes of admission among officers were ague, simple continued fever, and remittent fever ; and among the diseases with raised admission rates were enteric fever, ague, remittent fever, simple continued fever, dysentery, and diarrhœa, the ratios from influenza, small-pox, and respiratory diseases being lessened. Enteric fever and cholera were the chief causes of death ; the ratios from heat-stroke, dysentery, and remittent fever being raised, and those from pneumonia, circulatory diseases, hepatic abscess, and cholera lowered.

There was not more than one case of cholera at any one station. There were 19 cases of enteric fever in the field forces, 11 in the Tirah force. The greatest numbers of cases

of enteric fever were five at Lucknow and at Quetta and four at Agra. "The five admissions at Quetta occurred among the single officers of the 2nd Battalion, Lancashire Fusiliers. The cause was most probably the very insanitary condition of the mess kitchen. All the cases occurred within a very short time of one another."

On the whole the health of the women was better than in 1896, the chief feature of the following figures for 1897 being the decided fall in the death-rate :— Statistics of women.

Period.	Average annual strength.	Admission-rate per 1,000.	Constantly sick-rate per 1,000.	Death-rate per 1,000.
1886–95	31,881	815·2	32·1	17·00
1896	3,254	807·0	37·4	18·44
1897	3,203	768·3	38·2	15·30

The chief causes of admission were debility, ague, and the diseases peculiar to women. Among diseases which caused increased admission were cholera, ague, tubercle of the lungs, and dysentery; while from influenza, small-pox, respiratory diseases, and enteric fever, admission was lessened. Debility caused nearly 35 per cent. of the total sickness, and ague over 21 per cent.

The chief causes of death were puerperal affections and tubercle of the lungs. Among the diseases which gave increased mortality were cholera, dysentery, pneumonia, remittent fever, and puerperal affections. Mortality from enteric fever, respiratory diseases other than pneumonia, diarrhœa, hepatic abscess, and small-pox, was diminished. Puerperal diseases caused 10 per cent. of the total deaths, and tubercle of the lungs 8 per cent. There were only two cases of cholera among the women.

That the health of the children was worse than in 1896 may be seen in the following table :— Statistics of children.

Period.	Average annual strength.	Admission-rate per 1,000	Constantly sick-rate per 1,000.	Death-rate per 1,000.
1886–95	59,695	581·8	22·7	46·72
1896	5,790	573·6	24·9	45·60
1897	5,744	572·1	26·7	50·49

The chief causes of admission were ague and respiratory diseases. Among the diseases with raised admission-rates were influenza, cholera, remittent fever, eye diseases, ague, and bowel complaints; while admission from small-pox, whooping cough, and measles was lessened. Ague caused nearly 19 per cent. of the total sickness, and respiratory diseases nearly 12 per cent.

The chief causes of death were teething, diarrhœa, debility (including immaturity at birth) respiratory diseases, and convulsions. Among the diseases from which there was increased mortality were cholera, tubercle, ague, respiratory diseases, teething, debility, and bowel complaints. Mortality from small-pox, diphtheria and croup, enteric fever, convulsions, and remittent fever, was diminished. Teething and diarrhœa caused each over 15 per cent. of the total deaths, debility 13 per cent., and respiratory diseases 10 per cent.

Native Troops.

Sickness and mortality in 1897.

Though influenza and cholera were less prevalent, yet, owing to the arrival of an abundant monsoon after a prolonged period of drought, there was an increase of malaria, and therefore of sickness and mortality, in 1897 as compared with 1896. The sickness and mortality were also raised by the employment of a large body of men on active service :—

Year.	Average strength.	Ratio per 1,000.							
		Admissions into hospital.	Constantly sick.	Deaths from					Mortality, including absent deaths.
				Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All causes.	
1886–95 ...	123,302	976	34	1·32	1·34	3·02	·78	12·43	16·72
1896	128,286	763	29	·69	1·07	3·14	·42	10·20	12·57
1897	129,802	839	31	·52	1·04	2·73	·67	13·12	14·90

The chief causes of admission were ague and dysentery. Among the diseases with raised admission rates were enteric fever, dysentery, and ague. Among those with lessened rates were influenza, small-pox, scurvy, cholera, and respiratory diseases. Ague caused 41 per cent. of the total admissions.

The chief causes of death were pneumonia and remittent fever. Among the diseases which caused increased mortality were enteric fever, ague, and bowel complaints. Among those from which mortality was lessened were small-pox, cholera, remittent fever, respiratory diseases, and debility. Pneumonia caused 21 per cent. of the total deaths, and remittent fever 8 per cent.

The total number invalided for discharge was 1,649, and the chief causes of invaliding were debility, respiratory diseases, malarial fevers and venereal diseases.

If the following table be compared with that on page 42 it will be seen that the native soldier suffered less from cholera, enteric fever, ague, remittent fever, simple continued fever, tubercle of the lungs, diarrhœa, hepatitic affections, and venereal diseases ; equally from small-pox ; and more from influenza, respiratory diseases, dysentery, and scurvy, than his European comrade. These relations are usual, except with regard to cholera, ague, remittent fever, and small-pox.

Of the commands the Punjab was the most unhealthy, and it was slightly more unhealthy than in the previous year. Its death ratios from enteric fever, diarrhœa, tubercle of the lungs, and dysentery, were raised, while those from small-pox, respiratory diseases, and cholera, were lowered. Bengal had the highest constantly sick rate, the Punjab the highest admission and death-rates. The highest ratios of mortality from small-pox, ague, and tubercle of the lungs were in Bengal; the highest from enteric fever, remittent fever, pneumonia, and other respiratory diseases in the Punjab; the highest from cholera in Madras; and the highest from dysentery and diarrhœa in Bombay.

The following table shows the statistics of all the native troops serving in Burma and the Andamans. Of these troops in 1897, about 98 per cent. belonged to the Madras Army:—

Years.	Average annual strength present.	Ratio per 1,000.						
		Admissions into hospital.	Constantly sick.	Deaths from				
				Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All causes.
1891	11,401	1,676	76	1·75	2·98	1·84	4·03	36·31
1892	11,333	1,349	57	2·29	2·29	2·29	3·09	29·12
1893	10,326	1,092	48	·87	1·45	2·42	1·36	19·85
1894	10,500	809	35	1·43	·95	1·14	1·43	13·90
1895	9,952	827	37	·80	·50	·80	·80	10·55
1896	9,605	830	38	—	·94	·73	1·35	9·58
1897	8,661	802	35	·46	·46	·92	·23	6·58

The table shows that the death-rate has been reduced year by year. Sickness was lower than in 1896. A comparison of the health of the troops in the Burma Coast group

of stations with that of the troops in the Burma Inland group may be made by the use of the following table :—

Ratios of Geographical Groups.

* Including Group Extra-India.

The following statistics are those of the regiments stationed beyond the North West Frontier and in Baluchistan. The garrisons of Gilgit, Chitral, and the Malakand are not included :—

Year.	Average annual strength present.	Ratio per 1,000.						
		Admissions into hospital.	Constantly sick.	Deaths from				
				Cholera.	Remittent fever.	Pneumonia.	Dysentery.	All causes.
1897	9,188	1,182	34	—	·76	3·92	·65	15·35

If this table be compared with that for India on page 64, it will be seen that the statistics of the trans-frontier troops were considerably less favourable than those of India as a whole, a high death-rate from pneumonia being a salient feature.

Of the garrisons of Gilgit, Chitral, and the Malakand, Chitral was the most unhealthy, and the Malakand the least so.

Of the forces which took the field in 1897, wounds and violent deaths were most frequent in the Tirah force, which was constantly on the move and fighting ; but in the Tochi force, whose chief duty was to wait in an unhealthy valley, disease was most prevalent.

The table which follows shows that both for the decennium and in 1897, Groups II, III, and IV had high constantly sick ratios ; and that both for the decennium and in 1897 mortality from respiratory diseases was greatest in the Indus Valley. Cholera mortality was below the decennial figure in all the groups except Burma Coast, Deccan, and Southern India :—

		Ratio per 1,000 of Strength.											
		I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII.

	Respiratory diseases	·45	1·49	1·68	·98	3·18	2·99	7·86	2·46	1·72	1·07	1·82	3·09	32·3

In the Table on page 66, it may be seen that Assam had the highest admission ratios from enteric fever, dysentery, diarrhœa, hepatic congestion, and venereal diseases ; the Upper Sub-Himalayan group the highest from small-pox and tubercle ; the Indus Valley

the highest from ague and pneumonia, and nearly the highest from other respiratory diseases ; the Western Coast the highest from remittent fever and abscess of the liver ; Southern India the highest from cholera and simple continued fever ; and the Hills the highest from influenza, respiratory diseases other than pneumonia, and scurvy. The hill station of most influenza was Quetta. The presence of enteric fever and the prevalence of venereal disease in Assam are due to the number of Gurkha troops there.

Of the large stations throughout India with a strength of not less than 1,000, the following returned the highest death-rates :—Belgam 34·31, Dharmsala 25·60, Edwardesabad 24·78, Poona 21·05, Dehra Dun 20·75. The principal cause of death at Belgam and Poona was plague, at Edwardesabad pneumonia, at Dharmsala remittent fever, and at Dehra Dun tubercle of the lungs.

As quoted by the medical officer of the 10th Bombay Light Infantry, the finding of a board of medical officers assembled at Aden, by order of the general officer commanding, on the 4th November 1897 "to inquire into the causes of scurvy, fever, and dysentery, "prevalent among the native troops," was as follows :—

"That fever (including under that name intermittent, remittent, and simple continued fevers) is "very prevalent in Aden, and they are of opinion that it is due to persistent malaria, acting on con- "stitutions already weakened by indifferent food and insufficient vegetables, together with a certain "amount of nervous prostration produced by the long continued damp relaxing climate of the place. "Under the head of scurvy comparatively few cases are admitted, but there can be no doubt what- "ever that many of the cases of bowel complaints, including dysentery, for which the admissions are "usually much in excess of the average for the whole of India, are complicated by, if not primarily "induced from, a scorbutic state of the constitution. The board are of opinion that these conditions "are permanent, and that a regiment suffers materially in health, physique, and general stamina by "prolonged residence in this place, where malaria is always present (there is no marked malarial "season, as in India generally), and where the want of fresh vegetable food and good water is severely "felt.

"With regard to the last remark concerning water, they desire to point out that all the water used "for drinking purposes is distilled from sea-water, and consequently has but little vitality or freshness "in it, a condition which tends to produce dyspepsia, or a flaccid, inert condition of the digestive "system, leading to a state very appropriate for the setting up of bowel complaints, and this may "have no small effect on the excessive number of cases admitted under the head of dysentery.

"On the whole, the board are of opinion that nothing but harm is likely to result from the retention "of a regiment in Aden for a longer period than two years."

Principal Diseases: Influenza.—Attention having been directed to the health statistics of India, of the commands, of the geographical groups, of stations, and of regiments, it will be convenient now to consider some of the chief diseases. Influenza decreased much, there having been 695 cases, 5·4 per 1,000 of strength, against 1,369 cases, 10·7 per 1,000 of strength, in the preceding year. This number of admissions for 1897 is the lowest that has been returned since the disease first invaded India in 1890. The geographical groups affected both in 1896 and in 1897 were II, IV, V, VI, VII, VIII, IX, XI, XII ; III was affected in 1896, not in 1897, X in 1897 not in 1896 ; while I has had no case since 1892. In proportion to strength the Hills group was, as in the previous year, most severely affected ; and the greatest number of cases also occurred in that group. The following table shows the monthly progress of the disease since its beginning in 1890. The maximum month varied from year to year, but over the period as a whole most cases occurred in April and March, and fewest in October and September :—

Years.	Number of Admissions into Hospital each month.												Total.	Admitted per 1,000 of Strength.	Died per 1,000 of Strength.
	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.			
1890 ...	1	8	2,460	5,118	492	82	55	—	—	—	1	—	8,217	64·3	·41
1891 ...	—	—	1	—	105	259	123	106	51	22	17	215	899	7·0	·09
1892 ...	681	371	511	149	40	5	5	7	—	1	7	18	1,795	14·1	·15
1893 ...	8	28	65	99	95	13	9	7	—	3	53	404	784	6·2	·20
1894 ...	159	203	232	384	143	11	5	—	1	1	5	11	1,155	9·0	·16
1895 ...	26	28	53	76	110	25	60	57	19	17	31	·408	910	7·0	·08
1896 ...	372	196	397	35	22	11	33	57	53	39	82	72	1,369	10·7	·30
1897 ...	97	61	100	117	84	79	22	—	42	67	23	3	695	5·4	·04
Total	1,344	895	3,819	5,978	1,091	485	312	234	166	150	219	1,131	15,824	15·4	·18

The greatest number of cases occurred at Quetta, Bolarum, and Lucknow. At the first named station the disease was present during the first seven months of the year; while at Bolarum it was confined to March, April, and May and at Lucknow to the last quarter of the year. The following table shows that in 1897 the native troops, though somewhat more severely affected than the European troops, were, as usual, considerably less severely affected than the prisoners :—

Years.	Per 1,000 of Average Strength.											
	Influenza.						Pneumonia.					
	European Troops.		Native Troops.		Prisoners.		European Troops.		Native Troops.		Prisoners.	
	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.

1894	3·4	·01	9·0	·16	41·0	·43	3·7	·75	12·9	2·87	15·4	4·31
1895	7·8	·03	7·0	·08	20·3	·15	4·4	·51	17·5	4·20	16·4	4·00
1896	11·5	·11	10·7	·30	37·6	·60	5·2	·64	15·3	3·14	19·1	4·34
1897	4·0	·01	5·4	·04	8·4	·21	3·4	·60	13·0	2·73	15·6	4·24

It also shows the relation of the pneumonia death-rate year by year to the admission rate from influenza. Of course, the presence or absence of influenza is not the only circumstance which influences the pneumonia death-rate. Another powerful factor is the occurrence or non-occurrence in the year of exposure on field service.

Cholera.—There were 109 cases of cholera with 68 deaths, against 132 cases with 88 deaths in the preceding year. The admission-rate was 0·8 per 1,000 against 1·0, and the death-rate 0·52 against 0·69. Cases occurred in every month except December, the maximum months being July and August. The greatest number of cases occurred in the Deccan and Southern India. Among stations Secunderabad and Bellary had most cases, 15 and 12 respectively ; the other stations affected having less than a dozen, and most of them less than half-a-dozen, each. The regiment chiefly affected at Bellary was the 1st Madras Lancers, and the disease broke out in a bazar adjoining the regimental lines. Cholera was also found to be present in a village near the first camping ground, and the medical officer of the regiment contracted a fatal attack while looking up the cases in the village. The next camp-movement stopped the disease.

Small-pox.—There were 53 cases of small-pox with 6 deaths, against 148 cases with 13 deaths in the preceding year. The admission ratio was 0·4 per 1,000 against 1·2, and the death ratio 0·05 against 0·10. In the Upper Sub-Himalayan group the cases bore the highest proportion to strength. The greatest number of cases occurred in Upper Sub-Himalayan, Deccan, and Indus Valley groups. Among stations Meean Meer had 10 cases, the highest number at any one station ; and no regiment had more than three cases, except the 32nd Pioneers, which had seven.

Ague, Remittent Fever, Simple Continued Fever.—To ague was due over 41 per cent. of the sickness of the native army. Owing, no doubt, to the abundant rainfall following drought, the admission rate from ague rose very considerably in 1897, from 276·2 to

346·9 per 1,000. The Indus Valley was the most malarious group, and the Burma Coast, as in the previous year, the least malarious ; and the most malarious months were October and November, and the least malarious month February. Remittent fever caused 8 per cent. of the total deaths, and prevailed most in August, June, November, and September. The proportion of cases returned as simple continued fever is much lower in the native army than in the European ; but it is pretty certain that many cases which in the latter would be so returned are in the former called ague. The simple continued fever of the native army was high in March, but fell again, began to increase once more in June, and reached its maximum in October. This was quite different from its distribution in the preceding year.

Enteric Fever.—The ratio of admission from enteric fever in the native army in 1897 was 0·4 per 1,000 of strength, and the death-rate 0·12, against 0·1 and 0·04 in the previous year. The corresponding decennial ratios of 1886—95 are 0·2 and 0·08. The following table shows that the ratios for European troops are very unlike those for native troops and prisoners :—

	1886–95.		1897.	
	Admissions.	Deaths.	Admissions.	Deaths.
European troops	19·6	5·28	32·4	9·01
Native troops	·2	·08	·4	·12
Jail population	·3	·12	·3	·13

The next table indicates the fact that the total fever mortality in the two armies is not the same in amount, which indicates that the difference is not altogether a mere matter of diagnosis :—

Causes of Death.	Died per 1,000 of Average Strength.		Relative Liability in Percentages.			Percentage in Deaths from all causes.	
	European Troops.	Native Troops.	European Troops.	Native Troops.	Total = 100.	European Troops.	Native Troops.
Ague	·41	·65	39	61	100	1·8	5·0
Remittent fever	·60	1·04	37	63	100	2·6	7·9
Simple continued fever	·01	·03	25	75	100	·1	·2
Enteric fever	9·01	·12	99	1	100	39·3	·9
Total	10·03	1·84	84	16	100	43·8	14·0

The total fever mortality among the native troops in 1897 was to the total fever mortality among European troops as 1 : 5·5. For the period 1886—95 the corresponding ratio was 1 : 2·6, and for 1896 it was 1 : 4·2. Again, among the European troops 44 per cent. of all deaths in 1897 were from fevers ; only 14 per cent. among native troops. As the death-rate of European troops from enteric fever in 1897 was nearly five times as great as that of native troops from all kinds of fever, it appears, whatever may be the nature of the remittent and continued fevers from which native soldiers died, that native soldiers and prisoners were less liable to enteric fever than European soldiers.

The question of the immunity, or apparent immunity, of natives of India as regards enteric fever, has been frequently discussed in former reports. On page 71 of the report for 1896 were noticed the assertion that the blood of natives of India over the age of early childhood re-acted to Widal's test, and the conclusion therefrom drawn that the majority

of adult natives had passed through enteric fever ; and it was there shown that this had by no means been proved. It seems that a similar assertion had been made regarding the blood of negroes in America, and that the accuracy of the observation is now denied.

A few more observations have been published regarding the relation of the darker-skinned races to enteric fever. In Algeria the native Arabs are said to be a hundred times less liable to enteric fever than the French soldiers. One of the medical officers who write in the special medical part of the report of the Chinese Imperial Maritime Customs is of opinion that characteristic enteric fever sometimes occurs among the natives of China, while one states that he has never seen a pure case among them. On the other hand, the Japanese soldiers appear to have suffered from the disease during the late war between China and Japan, 131 cases and 24 deaths having been officially recorded. It has been reported that enteric fever is common in Bombay, but that among natives bowel symptoms are but slightly marked and the disease is not so fatal. It is, however, a fact that year after year Bombay exhibits a comparative rarity of enteric fever in its European garrison, and that for at least three years no cases have been returned from its native garrison. A good deal more must be scientifically known about the natives of malarious countries before the statement that they are less liable than others to enteric fever can be critically considered. Even if there be some references to this point in Italian medical literature, it is not certain that the conclusions arrived at would hold good for darker races.

In the whole native army of India, 51 cases with 15 deaths were returned as enteric fever, as against 19 cases with 5 deaths. In only three cases were *post-mortems* obtained ; and the lesions described support, or do not contradict, the diagnosis. The greatest numbers of cases occurred at Kila Drosh (Chitral), Wana, and Manipur.

Plague.—In 1896 there were two cases of plague with one death ; in 1897, one hundred and thirty-one cases with eighty-two deaths.

Respiratory Diseases.—Both morbidity and mortality from respiratory diseases were less than in 1896, and were also unusually low :

Period.	Ratio per 1,000 of Strength.			
	Respiratory Diseases.		Pneumonia.	
	Admissions.	Deaths.	Admissions.	Deaths.
1886–95	50	3·75	13	3·02
1896	43	3·72	15	3·14
1897	38	3·23	13	2·73

Respiratory diseases are the chief cause of death in the native army, and in 1897 over 24 per cent. of all deaths were due to them. For respiratory diseases other than pneumonia the highest admission ratios were those of the Hills and the Indus Valley, and the lowest that of the Deccan. Of commands the Punjab had the highest death-rate, and Madras the lowest.

Pneumonia.—The admission and death ratios from pneumonia, as may be seen from the table given in the preceding paragraph, fell considerably ; and were no longer, as in 1896, above the decennial ratios. In the table on page 69 is displayed the relation from year to year between pneumonia and influenza. The admission ratio was highest, as usual, in the Indus Valley ; and in the death-rate the Indus Valley thoroughly maintained its primacy. Both in the Indus Valley and in the Hills, pneumonia was most prevalent in the cold months, and the same was the case for India as a whole.

Dysentery and Diarrhœa.—From dysentery the admission-rate was much, and the death-rate considerably, higher than in the preceding year. The highest admission ratios were

in the Punjab command and the Assam group ; the highest death-rates in the Bombay command and the Assam group. The reason why the ratios of India are higher than those of any of the commands is that under the head of India is included field service, and field service gave rise to much dysentery. The death-rate of native troops from dysentery was to that of European troops as 1 : 3·8 ; and the percentage of dysentery in total cases of death was 5·1 in the case of native troops, and 11·0 in the case of European troops. Again, the case mortality of native troops was 1·00 per cent., while that of European troops was 5·32. The admission rate of native troops was, however, as in the previous year, much higher than that of European troops, 66·4 to 45·7.

The admission and death ratios from diarrhœa also rose in the year under review.

Venereal Diseases.—The following table is given to compare with the corresponding one for European troops on page 61.

Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Diseases.	Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Diseases.
1877	11·5	5·3	26·7	1888	13·5	5·4	31·5
1878	16·3	5·8	37·5	1889	16·6	6·4	38·9
1879	16·5	7·0	37·1	1890	16·0	6·9	41·1
1880	15·0	5·8	33·3	1891	13·6	6·9	37·9
1881	17·9	7·2	39·5	1892	14·1	7·9	39·6
1882	14·7	5·9	34·4	1893	13·3	9·0	36·4
1883	13·0	6·5	31·6	1894	13·8	8·2	32·3
1884	11·0	5·3	27·9	1895	13·1	7·3	31·3
1885	11·2	5·9	30·1	1896	15·5	8·9	37·2
1886	13·7	6·0	28·1	1897	16·1	9·0	40·8
1887	12·6	6·1	27·4				

The figures for India are not available for the years before 1877. All the venereal ratios of native troops run at a much lower level than those of European troops ; and they have remained comparatively steady during the years of which the statistics are given.

A comparison of Tables on pages 42 and 64, will show that, leaving the Hyderabad Contingent out of account, the lowest ratios for both European and native troops were those of the Punjab Command, and the highest those of the Bengal Command. In all the commands the ratios of native troops were much lower than those of European troops.

Whilst among the European troops an average strength of 68,395 gave 33,219 admissions, in the case of native troops an average strength of 129,802 gave only 5,295 admissions. In other words, there were only 41 admissions for every 1,000 men among native troops, against 486 for every 1,000 men among European troops.

The admission rate was 3·7 per 1,000 more than in 1896. There were 12 deaths and 106 invalidings directly due to veneral disease. In 25 out of 184 stations the admission rate from secondary syphilis was over 20 per 1,000 of strength, and in 36 it was over 10 per 1,000.

Beri-Beri. Strongylus Duodenalis.—Of the 137 cases returned as beri-beri, 135 occurred in Madras regiments, especially the 20th, the 19th, and the 9th infantry regiments. The Madras command accounted for 18 out of the 20 deaths ; 3 in Burma and 15 in the peninsular part of the command. A considerable amount of doubt still attaches to the diagnosis of these Indian cases.

Jails.

Sickness and mortality in 1897.

The drought, with resulting famine, continued into the first-half of 1897 from 1896, and was followed by a retarded but copious and well-distributed monsoon. In the period of drought cholera was prevalent here and there; while after the onset of the rains cholera, malaria, and dysentery attacked the people weakened by want of food, and found them an easy prey. Naturally, the health statistics of prisoners, and especially the death-rate, were unfavourably affected:—

Year.	Average strength.	Ratio per 1,000.									
		Admissions into Hospital.	Constantly Sick.	Deaths from							
				Cholera.	Remittent Fever.	Dysentery.	Diarrhœa.	Respiratory Diseases.	Phthisis Pulmonalis.	Anæmia and Debility.	All causes.
1886–95 *	960,973	1,097	39	2·74	1·49	6·80	2·82	5·85	2·50	2·52	32·20
1896 * ...	110,186	983	41	1·27	1·07	5·91	1·98	5·27	3·08	1·42	27·68
1897 * ...	118,107	1,045	41	3·94	1·08	11·07	3·17	5·19	3·02	2·35	38·75

* Excluding subsidiary jails.

The chief causes of admission to hospital were ague, dysentery, abscess, &c., and diarrhœa. Among the diseases with raised admission rates were cholera, ague, scurvy, debility and dysentery; while the rates from influenza, remittent fever, simple continued fever, tubercle of the lungs, and respiratory diseases were lowered. Ague caused 36 per cent. of the total sickness, and bowel complaints 17 per cent.

The chief causes of death were dysentery, pneumonia, cholera, and diarrhœa. Among the diseases with increased mortality were cholera, dysentery, enteric fever, debility, diarrhœa and gangrene. Among those with lessened mortality were tubercle of the lungs and pneumonia. Dysentery caused 29 per cent. of the total deaths, pneumonia 11 per cent., and cholera 10 per cent.

The following statement shows for each administration, except the Andamans, the proportion of prisoners in 10,000 of the population. Some of the prisoners of each province have been transported to the Andamans, though in the case of Bombay such transportation was restricted on account of plague; and these are necessarily excluded from the calculations, so that the ratios are all somewhat too low:—

Administrations.	Period.	General Population according to Census of 1891.	Prisoners.		
			Average Number.*	Proportion per 10,000 of Population.	Deaths per 1,000 of Average Strength.*
Burma	1896	7,605,560	14,460	19·0	18·19

* Excluding subsidiary jails.

The prisoners of the Central Provinces, Madras, Burma, Berar, and the North-Western Provinces and Oudh were more unhealthy than in the previous year.

In 1897 the three most unhealthy administrations were, in order, the Central Provinces, Assam, and the Andamans, and the three most healthy were, in order, Berar, Burma, and the Punjab.

As compared with the decennial ratios, cholera mortality was increased in Assam, still more in Bombay, and most of all in Madras ; dysentery mortality was increased in the Andamans, Bengal, the North-Western Provinces and Oudh, more in Madras, still more in Berar, and most of all in the Central Provinces ; diarrhœa mortality was increased in the North-Western Provinces and Oudh, Bombay, Berar, and especially in the Central Provinces.

Mortality from respiratory diseases was increased in the North-Western Provinces and Oudh, Berar, Madras, and still more in the Central Provinces ; phthisis mortality rose in all the provinces except Burma and Assam, and more especially in the Central Provinces and Madras ; and the total mortality increased in the North-Western Provinces and Oudh, Bombay, still more in Berar, still more in Madras, and most of all in the Central Provinces.

It will be noticed in the above table that the Punjab death-rate is not only the lowest of the administration rates, but is also the most favourable as compared with its decennial ratio ; while in both respects the Central Provinces death-rate is its opposite. The difference between the two rates is nearly 119 per 1,000 per annum. The use of prophylactic doses of febrifuges is extending, but the actual distribution of the drugs to the prisoners requires more careful supervision.

Andamans.—The Senior Medical Officer reports that the meteorological conditions of the year were peculiar, and unfavourable to the health of the convicts. Heavy rain in May was followed by a break of a month, and then by an unusually abundant monsoon, the consequence being prevalence of fever and dysentery. Even the women prisoners suffered severely from the fever, though they worked mostly under shelter, drank boiled water, and took prophylactics. He concludes as follows :—

" In recent years many important improvements have been made which are likely to favourably " affect the health of the convicts. Two large hospitals have been built in excellent sites at Bamboo " Flat and Viper ; wells and tanks have been more carefully protected ; and a Larymore boiler has " been installed in every important station. There is also a great improvement in the rice supply, " which is now obtained from Rangoon, and is much superior to the coarse rice formerly obtained " from Bengal. The Settlement gardens have been considerably developed, and the vegetable supply " much improved."

Burma.—The decrease in average annual strength was mainly due to the release of convicts in honour of the Queen-Empress's Jubilee. Notwithstanding the diminution in the number of prisoners, every jail in the province, except those at Thayetmyo, Toungoo, Shwebo and Tavoy, was overcrowded at one time or other during the year ; while in fifteen, including the central jail at Bassein, overcrowding was chronic, though in the majority of cases not to any great extent. The Inspector-General complains that the death-rates in the Burma jails are raised by the deportation to other provinces of the healthiest prisoners, and the return to their native land of such of the deported prisoners as lose their health. The jail at Moulmein has been notoriously unhealthy for many years, and is being reduced from a central to a district jail.

Assam.—The decrease in average strength was partly due to Jubilee releases. The reduction of the death-rate by over 10 per 1,000 of strength must be considered creditable in view of the facts that scarcity was prevalent, that the general health of the provincial population was bad, that ten of the prisoners lost their lives in the earthquake, and that many of the prisoners were exposed for a time to unusual hardships consequent on the demolition of buildings by the earthquake. The constantly sick and admission rates were also slightly reduced. These favourable results are attributed to an improved dietary, better clothing, restrictions placed on extramural labour, and the prophylactic use of quinine and iron.

Bengal.—The special causes unfavourably affecting the health statistics of the jail inmates in Bengal were, according to the Inspector-General, the impoverished physical condition, from famine and privation, of the prisoners on admission to jail ; the prevalence and severity of malarial fevers in the last three months of the year ; the increased number of prisoners admitted with short sentences for offences connected with the scarcity ; the release at the Jubilee of a large proportion of prisoners approaching the end of their sentences, health being usually better at the end than at the beginning of jail residence ; the withdrawal from the province, for war or plague service, of a great number of its most experienced medical officers, who in previous years had done much to improve the health of the prisoners. In many cases, unfortunately, the sanitary improvements which were being carried out in the jails were hindered on account of diversion of funds to meet the expense of repairs rendered necessary by the earthquake of the 12th June 1897. The damage caused by the earthquake deprived several jails of a portion of their permanent accommodation, which could ill be spared, because there was an abnormal increase in the jail population, producing over-crowding from time to time in many of the jails. The trial of the Pasteur filter in several of the jails has not yet been sufficiently extensive in time to warrant the drawing of conclusions.

North-Western Provinces and Oudh.—Although 8,267 prisoners were set at liberty on account of the Queen-Empress's Jubilee, the average annual strength was considerably in excess of that of 1896, and most of the jails were over-crowded. The general state of the public health and the meteorological conditions of the year were unfavourable to the prison population. Scarcity and famine, consequent on the continued drought of 1896, had so deteriorated the public health that a great proportion of the prisoners admitted were in an enfeebled condition. This is strikingly shown by a comparison of the death-rate among the convicts in jail for not more than six months, 44·4 per 1,000, with 29·29, the rate among the remainder. Such prisoners were ill-fitted to contend against the malarial influences engendered by the abundant monsoon rainfall of 1897, and the mortality of the last four months of the year was nearly as great as that of the earlier eight months.

Punjab.—Notwithstanding the release of 1,846 prisoners on account of the Jubilee, there was an increase in the average annual strength of the Punjab jails. The mortality of the second half of the year was much greater than that of the first, a reversal of what had occurred in 1896, the falling-off in the general health being attributed by the Inspector-General to the prevalence of malarial fevers consequent on heavy rainfall succeeding prolonged drought. No less than 50 per cent. of the deaths in 1897 occurred among prisoners who had been less than six months in jail, "a fact," says the Inspector-General, "plainly indicating the necessity for giving special consideration to the convict on admission "to jail, in respect to all matters affecting his health."

Bombay.—Owing to the failure of the crops in 1896 in certain districts, and the consequent general height of prices, there was a rise in the average annual strength; and a considerable number of the newly-admitted prisoners were in a somewhat weakly condition from lack of food. As no convicts could be sent to the Andamans because of the plague, the only considerable relief afforded to the strain on the accommodation was the release of 1,603 prisoners on the occasion of the Jubilee. All the jails, except those at Hyderabad, Kurrachee, and Karwar, were overcrowded at some time during the year, and in all but eight overcrowding was chronic. In some cases the overcrowding was very excessive. The restrictions imposed in consequence of the presence of plague rendered the customary transfers more than ordinarily difficult; but past experience has shown that it would be dangerous to agree with the Inspector-General that overcrowding is more apparent than real, because work-sheds are used as dormitories. No population can be expected to remain healthy if its members have to sleep in the same rooms in which they work.

Berar.—The effect of scarcity, famine, high prices, and immigration from the Central Provinces greatly augmented the criminal population in the Hyderabad Assigned Districts. All the jails were overcrowded; but it is satisfactory to note that there was no outbreak of epidemic disease in any one of them, and no excessive mortality. The Inspector-General of Prisons reports that, with the best results, the drinking-water in the Buldana jail was from June to the end of September boiled before being issued, having been purified and cleared by the use of alum and permanganate of potash.

Central Provinces.—Famine prevailed in nearly all the districts in the Central Provinces, and in spite of every effort made to exclude from the jails unfortunate wretches whom privation had driven to crime, the jails had to serve as poor-houses for a large number of criminal paupers. A common form of crime in the most severely affected districts was the theft of cattle to be killed and eaten by the starving thieves. Such an offence could not be treated as a petty theft, and the condition of the offenders too often precluded the infliction of corporal punishment in lieu of imprisonment. Every prison in the province was overcrowded, and in some instances the overcrowding was very excessive. Every endeavour was used to mitigate the effects of overcrowding by the utilisation of worksheds as dormitories, by the acquisition of neighbouring buildings, and by the erection of temporary sheds. Relief of the district jails by transfers to the central jails was possible to only a small extent, as the latter were also overcrowded. Fortunately material relief was afforded by the release on the 22nd of June of 1,646 prisoners on account of the Jubilee, and, by the Chief Commissioner's orders, of 923 short-term prisoners before the termination of their sentences. The Chief Commissioner calls attention to the effect of these releases on the statistics relating to sickness and death. The Inspector-General of Prisons says:—

"The reasons for the variations between jail and jail, and for the comparatively low provincial rate "of admission to hospital, appears to be that some medical officers prefer treating prisoners with "slight ailments, or in an anæmic condition, outside the hospital, to which they only admit prisoners

" suffering from severe ailments, or presenting suspicious symptoms, or incapacitated for movement.
" This was perhaps a wise course under the special circumstances of the year; indeed, in some jails
" it was a necessary course, as the hospitals were overcrowded."

The practice described should not make any difference in the admission rates, because the orders of Government are that all cases treated, whether in or out of hospital, should be entered as admissions in the hospital register.

Coorg.—There is only one jail in Coorg, that of Mercara. There was a fall in average strength due to Jubilee releases.

Madras.—The occurrence of high prices throughout the presidency and of famine in some areas was followed by a large increase in jail population. There was an increased sick rate and a very largely increased death-rate, the latter being mainly due to epidemics of cholera in the Rajamundry and Coimbatore jails. The death-rate of 1897, however, compares favourably with the death-rates of the last famine years, 1877 and 1878. The report of the Inspector-General of Prisons affords internal evidence that many improvements in the sanitation of the jails are still possible; and it may be hoped that the investigation which followed the outbreak of cholera at Rajamundry will lead to their introduction.

Mortality of prisoners and of troops compared.—A table is, as usual, here given to compare the mortality of prisoners in 1897 with that of soldiers. Taking the death-rate of European troops as unit, the death-rate of native troops will be represented by 0·6, and the death-rate of prisoners by 1·7. The mortality of prisoners was comparatively high as regards cholera, bowel complaints, spleen disease, anæmia and debility, respiratory diseases and tubercle of the lungs. Only from fevers was the European soldiers' mortality highest. The enormously greater liability of the prisoners to death from bowel complaints is well shown in the table. Taking the mortality of the native troops from fevers as 1, that of the prisoners is 1·2, and that of the European troops 5·4. Taking the mortality of the native troops from bowel complaints as 1, that of the European troops is 3·3, and that of the prisoners 16·9. Taking the mortality of the European troops from respiratory diseases as 1, that of the native troops is 4·6, and that of the prisoners 7·5. While the liability of the native soldiers to die from respiratory diseases was less than that of the prisoners, yet these diseases made up a larger percentage of the total deaths among native soldiers than among prisoners. The chief cause of death among European troops was fevers, among native troops respiratory diseases, and among prisoners bowel complaints. Of course, for obvious reasons, too much must not be made of the comparison here instituted:—

Causes of Death.	Died per 1,000 of Average Strength.			Relative Liability in Percentages.				Percentage in Deaths from all Causes.		
	European Troops.	Native Troops.	Prisoners.	European Troops.	Native Troops.	Prisoners.	Total 100.	European Troops.	Native Troops.	Prisoners.

* Enteric, intermittent, remittent, and simple continued fevers.

General Population.

General Remarks.—Vital statistics have been well called the foundation of sanitary effort. This description seems to be a very happy one, for not only does it indicate that reliable statistics are essential to the progress of the allied sciences of hygiene and pathology, but it implies the fundamental importance of vital statistics in the consideration of many economic problems. Unfortunately the subject is a difficult one, and it is too often also an uninteresting one. In India the inherent difficulty is increased, while any interest that might be aroused is diminished, by the inaccuracy of the figures. Not only are the returns imperfect, but the population figures, upon which computations must be based, are far from being correct.

The population figures are those obtained at the last census, and even when these were originally correct, the changes which must have taken place in them since 1891 render close reasoning in respect of ratios calculated upon them almost impossible. No amendment in the population figures is possible until after next census; and the corrections which are used in other countries to obtain precise intercensal figures cannot be generally applied with advantage in India.

The returns are certainly improving, and Local Governments and Administrations are alive to the importance of their continued improvement; but nothing approaching the actual facts can be obtained so long as the collecting agency in rural areas remains illiterate, and until sufficient pressure is put upon municipal bodies to enforce the bye-laws under which registration is legally compulsory in towns.

The abnormality introduced into the returns for 1897 by the occurrence of famine in many parts of the country renders any comparison with the figures of former years useless as an index of change in the quality of registration; but just as a traveller reaching an elevation in his path instinctively looks back over the country he has travelled, so a year of unusual statistics gives a fitting opportunity to glance at some of the tendencies exhibited by the returns relating to vital statistics in India since 1892, when the new census figures were first generally used. Little attempt is made to explain anomalies; this must be left to the provincial Sanitary Commissioners, who are in the possession of local knowledge and are able to make enquiries on the spot.

Births.—The following statement epitomises the birth statistics of 1896 and 1897, showing the urban and rural populations under registration, the number of children born, the ratios of the births per 1,000 in 1896 and 1897, with the average ratios of the previous five years, and the numbers of males born to every 100 females born:—

Birth Statistics.

Province.		Number of Municipalities and towns in which births were registered.	Number of rural circles in which births were registered.	Population under Registration. 	1897	93	179	2,538,033	30,060,268	32,598,301	935,845	28·7	41·6	20·8	103·9	+ 3·3	27·8
Bombay	1896	63	221	2,304,373	16,515,973	18,820,346	691,847	36·76	47·55	18·35	107·92	+ 5·07	35·41
	1897	63	220	2,304,373	16,515,973	18,820,346	629,693	33·46	44·11	11·29	108·42	- 6·38	35·51
Coorg	1896	*	5	15,511	157,544	173,055	4,606	26·62	32·11	20·70	97·68	+ 0·18	21·95
	1897	5	5	15,511	157,544	173,055	3,503	20·24	26·12	15·36	100·74	-29·79	24·18

It will be seen that although in every province, except Berar, the birth-rates of 1897 are lower than in the previous year, the relative positions of the provinces are not greatly altered—the Punjab and Berar are at the top of the list, and Coorg at the bottom. The North-Western Provinces and Oudh has, however, fallen below Assam and Lower Burma, and the Central Provinces below Madras.

The ratios registered in the past five years show a tendency to increase in every province, except the North-Western Provinces and Oudh, the Central Provinces and Berar. The falling off in Berar is not, however, sufficient to cause that province to lose its high position.

A feature of great interest is the very varying proportion of male and female births registered in the different provinces. In 1897 the percentage of male to female births ranged from 110·5 in the Punjab to 100·74 in Coorg, a higher percentage in the one case and a lower in the other than is generally recorded in countries where registration is supposed to be fairly accurate.* Simple explanations of high percentages may be offered: where the total birth-rate is low and the percentage of males born high, the births of females are not registered; and, where the birth-rate is fairly normal and the percentage is high, the births of females have been registered as the births of males. These simple explanations, no doubt, cover many cases, but by no means all.

An examination of the provincial returns for a series of years shows that the percentage figures in each province are fairly characteristic of that province; for instance, in the Punjab the percentage of male to female infants born during the last ten years has never been so low as 110, while in Madras during the same period it has never been so high as 105; meanwhile the lowest birth-rate recorded in the former province was 34·02 per 1,000 in 1891, and the highest in the latter, 32·4 in the same year.

Deaths.—The following statement gives certain details of the registration of deaths and shows the total mortality in the various provinces in 1896 and 1897, the urban, rural,

* In England and Wales, in 1896, male births were in the proportion of 103·6 to 100 female births, ranging in that year from 111·6 in Rutlandshire and 108 in Suffolk to 101·2 in Gloucestershire and 100·8 in Worcestershire. In the previous sixteen years the percentages varied between 103·3 and 104·1.—Registrar General's Report, 1896.

and total millesimal death-rates in these years, with the quinquennial averages, and the number of deaths of males for every 100 deaths of females :—

NOTE.—For population under registration, *see* preceding table.

Except in the Punjab, the death-rate was everywhere higher than the average, and in every province, except Bengal and the Punjab, the death-rates of 1897 were higher than the death-rates of 1896. As in the previous year, the highest death-rates were recorded in the Central Provinces, Berar, and Assam, and the lowest in Burma and Madras. A phenomenal rise in the death-rate in Coorg, from 26·43 per 1,000 to 50·03, raised that small province from the eighth place which it held in 1896 and holds among the quinquennial averages to the fourth place in 1897. The relative positions of the remaining provinces remain unaltered, except that a rise in their death-rates has placed the North-Western Provinces and Bombay above Bengal.

An examination of the death-rates of recent years shows that the provinces may be placed in three groups : where death-rates are very high, comparable with the highest registered in any European country twenty years ago, the Central Provinces and the neighbouring province of Berar, in both of which recent events have been disastrous to the public health ; where rates are low, comparable with those recorded in Prussia, at the present day, Madras and Lower Burma ; and third, where the rates are medium, from 30 to 35, comprising the remaining provinces. In Lower Burma, with improved registration,

the rates are steadily increasing; but in Madras, if the sudden rise in 1897 is excepted, the tendency seems to be towards a decline rather than towards a rise in the rates.

In former years the Central Provinces has furnished an exception to the rule that the average death-rates in towns are higher than the rates recorded in rural areas, but on account of the effect of famine and the flocking into the towns of the starving poor, the excess of rural mortality, which in 1896 had been reduced to ·56 per 1,000, has been changed to a deficiency of no less than 13·37 per 1,000. Elsewhere than in Bengal and the Punjab there was a marked rise in urban mortality as compared with 1896, and everywhere, except in Madras and the Punjab, the urban rates had increased in a greater degree than the rural—in Bombay, Assam, and Coorg the increase was very remarkable. In Madras the rural death-rate increased much more than the urban; and in the Punjab the mortality in towns fell out of proportion to the reduction in rural areas.

Turning now to the column showing the number of male deaths for every hundred female deaths reported, we find in 1897 that 105 males died for every 100 females that died in the Punjab, while in Lower Burma the percentage was 127. This great variation is not paralleled in the returns for England and Wales during the last fifty years, the extremes there having been 105·4 in 1849, and 114·5 in 1877. Indeed, in England from 1878 onwards the figures do not vary much from year to year, and from 1886 to 1895 the average was 112·1, with extremes of 111·1 and 113·6. Every province in India, except Madras, exhibits greater variation in the recorded percentages in the last five years, but when averages are struck the provinces arrange themselves into groups, again three in number—very high percentages, Lower Burma and Coorg; very low, Bombay and Madras; and medium, the remaining provinces. The high percentages in Lower Burma and Coorg may be accounted for by the annual immigration in search of work of coolies, among whom mortality is apparently very high. The percentage in Bombay is increasing steadily. In Madras a low percentage is in part explained by the fact that there is a considerable excess of females in the population. This factor, however, if the census figures are to be accepted as correct, is not influential elsewhere, for the excess of males in the Punjab is greater than in any province except Coorg, while the relative percentage of male deaths is lower than in any province except Madras and Bombay; and though females predominate in the populations under registration in both Bengal and the Central Provinces, the percentages of male deaths are higher in these provinces than in any, except Lower Burma, Coorg, and the North-Western Provinces and Oudh.

Indeed, omitting Lower Burma and Coorg, in Madras alone does the proportion of male to female deaths show any relation either to the varying excess of male births or to the excess of males in the populations as determined at the census of 1891.

With the remarkable exception of the Punjab, the death-rates of male infants in 1897 were everywhere higher than the death-rates of female infants; and, again excepting the Punjab, boys between the ages of one year and five years died at a greater rate in every province than girls of the same ages. As was to be anticipated, the infantile mortality was enormous in the Central Provinces and Berar, but there is a curious anomaly in the returns from these provinces. In England and Wales the records show that there are great variations in the mortality of infants from year to year, but that the variations in the proportion of the sexes dying is small; that is to say, if the mortality of male infants is high, the mortality of females is high also, and *vice versâ*;* and it would be expected that in the province where the death-rate of male infants was highest, female infants would die at the greatest rate; but this is not the case, for the death-rate of male infants in 1897 was highest in the Central Provinces, while female infants died at the greatest rate in Berar.

Major Dyson regards the greater mortality of males in Bengal as easy of explanation. "It is well known," he writes, "that male children are more difficult to rear than female "children, and adult males are more exposed to vicissitudes of climate and accident than "females." The statement that male children are the more difficult to rear does not, however, explain the phenomenon, and the questions arise, are adult males among the masses in Bengal, and in India generally, more exposed to vicissitudes of climate and accident than females? If they are, does this extra exposure compensate for the effects of premature marriage and maternity and primeval midwifery? Whatever the replies to these questions may be, it is a fact that the returns since 1892 show that at every age-period in Bengal, except 15–20, in 1893, and at every age-period in the

* Registrar General Report for 1896, p. xviii.

Central Provinces, the recorded death-rate of males is higher than the recorded death-rate of females. This is, however, not the case in other provinces. In every other province of India proper the female death-rate is higher than the male in the age-period 15–20; and in all these provinces it is the rule for the female rates to be the higher in the following age-period 20–30. Moreover, in Bombay, the Punjab, Berar, and Coorg it is invariable, while in other provinces it occasionally happens that females die at a greater rate than males in the age-period 10–15. That is to say, during the age-periods embracing adolescence and early child-bearing the female death-rates are higher than the male rates. In Burma, where marriage is deferred, the female death-rates are the higher in the age-periods 20–30 and 30–40.

Bengal and the Central Provinces have one factor in common, the female populations are greater than the male; but this predominance is more pronounced in Madras, where the female death-rates are always the higher in the age-periods 15–20 and 20–30, and, except occasionally in the age-period 10–15, at these ages only.

The returns from the Punjab are altogether exceptional; females die at a greater rate than males at every age-period, except in infancy, and in age-periods over 40; and in 1897 the extraordinary phenomenon, not observable in any provincial returns, since 1887 at any rate, of the death-rate of female infants being higher than the death-rate of male infants was recorded. The Punjab ratios may be explained by the female population at nearly all periods being under-estimated at the census.

The following statement shows the monthly incidence of mortality from all causes in each province:—

Statement showing the Deaths from all causes, according to Months, in the different Provinces of India during the year 1897.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.	RATIO OF DEATHS PER 1,000 OF POPULATION. 1897.	1896.

Everywhere, excepting Bengal, the Punjab, and Ajmere-Merwara, the numbers of deaths registered were greater than in 1896, the total excess aggregating 862,387. The months in which the greatest mortality occurred were November, October, and August, in the order given. By far the lowest mortality was registered in February, and this was followed, but at a great distance, by January and April. In comparing the monthly distribution of the mortality in the different provinces in 1897 with past years, no conspicuous irregularity is observable; maxima and minima occurred in the same months as in an ordinary year, but the figures are generally much higher.

In the following paragraphs some account is given of the salient features of registration in the different provinces:—

Bengal.—No change was made during 1897 in the system in force in Bengal for the collection of vital statistics. Registration is compulsory in towns; and in rural areas the particulars are collected by the village watchmen and registered by them at the

police outposts and stations. Inspecting officers of the vaccination establishment verify registers and report any errors or omissions that they may find. Errors are corrected and omissions are rectified, while suitable notice is taken of the neglect of the defaulting watchman or policeman. During 1897, 178,528 births and 124,204 deaths were enquired into, and it was found that 3,043 of the former and 1,944 of the latter had not been entered in the *thana* registers. The total number of persons, including watchmen and policemen, convicted of neglect in respect of registration in 1879 was 1,810, against 1,969 in the previous year ; on the other hand, there was an increase from 408, in 1896, to 463 in the number of persons warned.

The conditions affecting the vital statistics in Bengal in 1897 were peculiar, and, making every allowance for defects in registration, the results were extraordinary. The monsoon rains of 1896 ceased prematurely, so that the public health was unusually good during the last quarter of the year, owing to a great decrease in the ordinary mortality recorded under fever. Similar favourable conditions were maintained during the early part of 1897. But the drought, while it lessened fever mortality, led to widespread scarcity, merging in many places into famine. No less than fifteen districts are described by Major Dyson as famine-stricken, while in other four, though the extensive measures of relief necessary in the former were not required, test works were opened and a certain amount of gratuitous relief had to be given. The actual period of famine conditions extended from the beginning of October 1896 to ths end of September 1897. It would appear from the statistics that the scarcity was sufficiently great to check the birth-rate, but not great enough to raise the death-rate in the face of the other generally favourable conditions, for, of the various classified death-causes, only small-pox, dysentry, and diarrhœa and injuries* caused more deaths than in 1896, while fever, which generally causes rather more than two-thirds of the deaths, was only very slightly (about ·30 per 1,000) more fatal than in an ordinary year.

The total number of births registered was 2,625,844, as compared with 2,703,486 in 1896, and the birth-rate, which reached 38·03 per 1,000 in that year, fell to 36·94, which is, however, 3·11 per 1,000 in excess of the quinquennial average. The highest district birth-rates were recorded in Malda, 47·40, Noakhali, 44·71, and Murshidabad, a district affected by the scarcity, 44·64 ; while, excluding Calcutta, the lowest rates were recorded in the Sonthal Parganas, 29·62, a famine district, and Pabna, 28·97, a scarcity district. In the urban district of Calcutta the birth-rate was only 18·46, accounted for in part by the great excess of male population, and in part by defective registration. Among the towns, Jamalpore again heads the list with a birth-rate of 52·62, and in other ten the rates were over 40 ; but in the towns generally the birth-rates were lower than in the surrounding country ; the reasons given for this by the Sanitary Commissioner being the following :—

(1) Excess of the male over the female population.
(2) The existence of a large floating population.
(3) The custom of women leaving the towns to be confined in the country.
(4) Defective registration.

All these causes no doubt contributed in the small towns of Nalchiti, Dinajpur, and Jhalukati, where the lowest birth-rates, 11·94, 11·06, and 2·11 per 1,000, were recorded, and it would seem, in the case of the last-named at any rate, that defective registration is mainly to blame, for the birth-rate has been abnormally low for years past, and in 1897 four male births were recorded for every single female birth.

The percentage of male to female births in the province generally was 106; exceptionally high percentages were recorded in neighbouring districts of Calcutta (114), the 24-Parganas (112), Howrah (111) ; and Hooghly (111), possibly due, in view of the comparatively low birth-rates returned, to defective registration. In none of the famine districts, save Saran (110) and Shahabad (108), were the percentages abnormally high, nor was the percentage more than 107 in any district where the recorded birth-rate was above the provincial average.

The total number of deaths registered was 2,341,632, as compared with 2,428,830 in the previous year, and the death-rate was 32·94 per 1,000, against 34·17 in 1896, and a quinquennial average of 32·11. The highest district death-rate was 49·46 per 1,000, recorded in Chittagong, where not only were large numbers drowned by the storm-wave

* The death-rate from injuries was raised on account of the numbers who perished in the cyclone of the 24th October.

which swept over part of the district during the cyclone of the 24th October, but the privations and the pollution of the water-supplies which resulted were favourable to the development of fever and cholera.

It is an eloquent testimony to the efficacy of the relief measures that the next highest death-rates were only 48·12 in Hazaribagh and 46·48 in Lohardaga. These rates were followed by 42·46 recorded in Backergunge, which was unaffected by famine. The lowest district death-rates were 26·02, 24·42, and 23·88 per 1,000, registered, respectively, in Tippera, the 24-Parganas, and Singbhum.

The average rural death-rate was 32·83, as compared with 35·09 in the towns. In some of the latter the rates were very high, the highest having been 89·59 in Lohardaga, due mainly to cholera; 78·51 in Hazaribagh, where also cholera was very rife; 67·00 in Kotrung, due largely to dysentery and diarrhœa; 66·30 in Chatra, and 61·62 in Daltonganj, due in both cases largely to cholera; and 60·94 in Buxar, ascribed chiefly to fevers. In many of the towns the rates were low, the lowest having been 15·43 per 1,000 in Cossipore-Chitpur, 14·37 in Jhalukati, and 14·20 in Maniktala.

Of the various sects the small Christian and Buddhist communities had the lowest death-rates, 21·69 and 29·08 per 1,000 respectively; Muhammadans and Hindus died at the rates of 33·60 and 32·52 per 1,000; while the "Other Classes," most of whom live in the Southal Parganas and Lohardaga, died at the millesimal rate of 35·63.

The smallest numbers of deaths were recorded in February, June, and January, and the largest numbers in November, August, and December.

The age distribution of mortality is interesting. At all age-periods, save those from 10 to 20, the rates were lower than in 1896; the comparatively low infantile mortality is, of course, in part explained by the defect in the number of births, but in a famine year it is curious that the death-rate of the aged should be much lower than usual.

Infants died at the rates of 239·11 and 194·41 per 1,000 among males and females respectively; and boys and girls between one year and five years of age at the rates of 45·79 and 38·72 per 1,000. As is usual in Bengal, the death-rates of males were higher at all ages than those of females, the respective averages having been 35·87 per 1,000, as compared with 30·03.

Port of Calcutta.—The number of European seamen reported to have arrived in the port during the year under review was 19,608, against 17,053 in 1896, and the average daily population was 1,202, or 78 more than in the previous year. The total number of deaths in hospital was 26, equal to a death-rate of 21·63 per 1,000 as compared with 28·46, the fall being chiefly due to cholera, from which 11 deaths (9·15 per 1,000) occurred in 1897, against 18 (16·01 per 1,000) in 1896.

Among the native floating population the deaths registered during the year numbered 208, against 219 in 1896, the death-rates for the two years having been 8·11 and 8·54 respectively.

Assam.—The arrangements for the registration of vital statistics in Assam, and the area of their collection, comprising the plains districts of the Brahmaputra and Surma Valleys, selected tracts in the Khasi and Jaintia Hills, and in the Garo Hills and the station of Kohima, remained unaltered during the year. Only in the Surma Valley and in Goalpara are the registrars paid, elsewhere village headmen, on whom but little pressure can be brought to bear, are employed. Registers are checked by Inspectors of Vaccination and by the police, but, except in the district of Goalpara, apparently in a perfunctory way. In the towns, where registration is supposed to be compulsory, there were 241 prosecutions for failure to report, against 140 in 1896, and this increase in activity seems to have effected some slight improvement, but in many of the towns, in some of which registration is peculiarly bad, no action was taken under the Acts. In the Garo Hills the birth-rate rose from 37·15 per 1,000 to 40·07; and the death-rate from 33·58 to 51·83. In Kohima the birth-rate rose from 28·64 to 34·25; and the death-rate from 28·07 to 55·59, including 77 deaths which occurred in the dispensary. In the Brahmaputra and Surma Valleys and the Khasi and Jaintia Hills the total number of births was 163,617, as compared with 169,172 in the previous year; and the birth-rate was 32·59 per 1,000, against 33·69, the highest on record, registered in 1896, and 31·39 the mean of the preceding quinquennium. As in previous years, the birth-rate in the Surma Valley, 34·86, was higher than that recorded in the Brahmaputra Valley, 30·39; but the highest district rate was recorded in Goalpara, 45·12; and the rate in Lakhimpur, 35·17, was the same as that recorded in Sylhet. In Goalpara, where for the last three years the highest rate has been registered,

the continued good results are attributed to the personal interest taken in the work by Mr. Ward, the District Superintendent of Police. The lowest rates were 25·53, 25·45 and 19·77, registered respectively in the Khasi and Jaintia Hills, Kamrup and Nowgong. In Nowgong the ravages of *kala azar* have doubtless reduced the population, and the *gaonburas* who collect the statistics are reported to have often been so ill as to be unable to take their reports to their stations.

Among the towns the highest birth-rates were recorded in Golaghat, 42·97 per 1,000, Karimganj, 41·51, Dibrugarh, 40·20, and Hailakandi, 40·00, while the lowest were registered in Silchar, 16·08, Dhubri, 14·30, and Maulvi Bazar, 12·17.

The average percentage of male to female births was 108·13, ranging in the districts from 105·74 in the Khasi and Jaintia Hills to 111·28 in Sibsagar.

The year was an extraordinarily unhealthy one, and the number of deaths was 254,093, exceeding the previous record number by no less than 71,676. The death-rate was 50·61 per 1,000 as compared with 36·33, the highest previously recorded, in 1896, and 31·45 the quinquennial mean. The deaths from fevers were more than 10 per 1,000 in excess of the mean; the death-rate from this cause being less than the mean in only two districts, Goalpara and Sibsagar. In every district, except Sylhet, Nowgong, Lakhimpur and the Khasi and Jaintia Hills, cholera was more prevalent than usual, the average death-rate throughout the province being nearly doubled. Small-pox also was more fatal than usual everywhere, except in the Surma Valley and in Goalpara. Dysentery and diarrhœa were more fatal than usual in every district. The highest district death-rates were recorded in Cachar, 61·18 per 1,000, Sylhet, 53·02, and Goalpara, 50·53; and the lowest in Darrang, 46·74, Sibsagar, 42·95, and Lakhimpur, 41·72.

The nominal causes of the exceptional mortality have been indicated above, but the reasons which determined the activity of these causes are not apparent. The earthquake has been blamed; but the Sanitary Commissioner points out that the mortality was generally least affected in places where most damage had been done by the earthquake, and *vice versâ*. It seems, however, impossible to doubt that the suffering and exposure resulting from the floods and other effects of the earthquake could have failed to affect the public health very injuriously. This is borne out by a comparison of the relations of the death-rate in 1897, in the months before and after the earthquake, with the corresponding figures in other years. It must be remembered that the last seven months are generally more unhealthy in Assam than the first five, and that the first five months of 1897 were peculiarly unhealthy. But if the total death-rate had borne its normal relation to that recorded up till May, it would have been only about 44 per 1,000, whereas it was actually 50·61, and it seems not unfair to ascribe part of the excess to the effects of the earthquake.

The average death-rate in rural areas was 50·26 per 1,000, against 66·71 in the towns. Among the latter, extraordinarily high rates were recorded in Tezpur, 125·17, Dhubri, 112·12, Karimganj, 111·97, Hailakandi, 109·23, Barpeta, 106·84, and Golaghat, 101·31. In Tezpur, cholera, fevers and dysentery and diarrhœa were exceedingly fatal; in Dhubri the high death-rate was mainly due to cholera and dysentery and diarrhœa; in Karimganj and Hailakandi, to fevers; in Barpeta, to cholera and fevers; and in Golaghat, to dysentery and diarrhœa. The lowest urban death-rates were 30·43, 24·26 and 22·86, registered, respectively, in Maulvi Bazar, Shillong and Jowai, small towns in which the mortality from fever was low and cholera was either altogether absent (Jowai) or only a few cases occurred.

Among the different communities, the highest death-rate, 66·48, was recorded for "Other Classes," and the lowest, 36·88, for the comparatively small community of Christians; Muhammadans and Hindus died at the rates of 55·28 and 45·60 per 1,000.

The death-rate among male infants was 251·81 per 1,000, and among females 236·42; and among boys and girls between one year and five years the rates were 62·40 and 61·46 respectively. At all periods, except those between 15 and 30, the male death-rates were the higher, the average mortality among males having been 51·20 per 1,000, against 49·97 among females.

North-Western Provinces and Oudh.—The conditions of the year in these provinces, as elsewhere, were entirely abnormal; the birth-rate was diminished on account of the severe scarcity that prevailed in many districts during the previous year, while the death-rate was increased owing to the effects of the famine, which was widespread in 1897. In the beginning of the year there were nearly half a million persons in receipt of aid in

thirty-seven districts, of which twelve were recognised officially as famine-stricken.* The numbers assisted increased rapidly till a maximum of 1,696,722 was reached on the 27th of February; in March the numbers fell off on account of the harvesting of the spring crops being in operation, but large numbers returned in April and May, and the total did not again diminish until the approach of the rains in June. In September relief works were closed, although gratuitous help was continued in the villages until the middle of October, when the famine was practically at an end. In the margin is given a statement, taken from the resolution by the Local Government on the provincial Sanitary Report, showing the actual numbers on relief at certain dates throughout the famine of 1897.

Dates.	Numbers on relief.
2nd January	496,879.
6th February	1,400,243.
6th March	1,542,122.
3rd April	1,021,126.
1st May	1,289,862.
5th June	1,554,844.
3rd July	861,408.
7th August	542,085.
4th September	416,116.
2nd October	168,337.

The total number of births recorded was 1,458,947 against 1,660,387 in 1896, and the birth-rate fell from 35·40 per 1,000 in that year to 31·10 in 1897, as compared with a quinquennial average of 37·42. The highest district rates were 50·74 per 1,000 in Bulandshahr, 47·48 in Etah, 46·02 in Aligarh, 43·73 in Muzaffarnagar, and 41·78 in Meerut, all prosperous districts. The lowest rates were 13·76 per 1,000 in Banda, 19·49 in Hamirpur, 21·0 in Jhansi, 21·32 in Azamgarh, 22·78 in Fatehpur, and 23·61 in Hardoi, all districts which had suffered more or less from scarcity in 1896. In only twelve districts were the births more numerous than the deaths. The percentage of male to female births rose from 108·86 to 108·98, ranging in the districts from 118·09 in Naini Tal to 102·69 in the neighbouring district of Garhwal. In some of the famine districts the percentages were very high, *e.g.*, Banda 116·93, Cawnpore 112·33, Hardoi 110·69, but almost as high percentages were registered in these districts in 1895, while in districts where there was no famine, *e.g.*, Meerut 112.43, Saharanpur 112·24, high percentages have been registered for years past.

The number of deaths recorded was 1,897,592, as compared with 1,562,894 in 1896, and the death-rate was 40·46 per 1,000, as compared with 33·32 in the previous year, and was 7·83 per 1,000 higher than the mean of the preceding five years. Although the death-rate was so much higher than the average, it must be reckoned a low rate when the circumstances are taken into consideration, for it is actually more than 2 per 1,000 less than in 1894, when the millesimal rate, owing to a widespread epidemic of cholera and great mortality from fever, was 42·51. The highest district rates were 62·07 per 1,000 in Hamirpur, 59·71 in Jalaun, 55·77 in Bareilly, 55·55 in Agra and 55·09 in Fatehpur, and high rates were registered also in Mirzapur, Hardoi, Banda, Lucknow and Rae Bareli. All these districts were severely afflicted by famine, except Agra and Bareilly, in which a fatal and persistent form of malarial fever was present and occasioned a higher mortality than might otherwise have been the case had not the population of these districts shared in the actual scarcity which the high price of food-grains occasioned. The lowest rates were 23·67, 24·10 and 24·63 per 1,000, registered, respectively, in the hill districts of Garhwal, Almora and Dehra Dun.

In rural areas the average death-rate was 39·86, as compared with 48·55 in the towns, in many of which the rates were enormously raised by the influx of the infirm and starving poor. This was particularly the case in most of the following towns, where exceptional rates were recorded:—Hardoi (108·05), Kosi (105·42), Sandila (91·06), Utraula (91·02), Pilibhit (89·71), Kunch (83·38), Orai (81·85), Fatehpur (79·98) and Lalitpur (76·84). In Hardoi the deaths from fever were very numerous, while the enormous death-rate of 46·00 per 1,000 from dysentery and diarrhœa was recorded. These diseases caused high death-rates also in Sandila, Kunch and Fatehpur. In Pilibhit fevers were extraordinarily fatal, 88·17 per 1,000, and in Lalitpur, Sitapur and Fatehpur exceptionally high death-rates of 42·12, 21·57 and 20·96 per 1,000, respectively, were registered under the heading "All other causes." Kosi, Utraula and Orai are comparatively small towns, and the sanitary condition of the first has been the subject of a special report to the local Government. The lowest urban death-rates were 25·75, 25·13 and 24·83 per 1,000, recorded, respectively, in Basti, Sardhana and Bahraich.

---

* Cawnpore, Banda, Hamirpur, Allahabad, Jhansi, Jalaun, Jaunpur, Lucknow, Unao, Rae Bareli, Sitapur and Hardoi were recognised as famine-stricken in the beginning of the year. In January and February the following seven were added to the list:—Agra, Etawah, Mirzapur, Bara Banki, Gorakhpur, Azamgarh and Fatehpur. The following eighteen districts are described as "scarcity districts":—Dehra Dun, Muttra, Farukhabad, Mainpuri, Etah, Bareilly, Bijnor, Budaun, Moradabad, Shahjahanpur, Pilibhit, Benares, Basti, Kheri, Fyzabad, Gonda, Sultanpur and Partabgarh.

Among the sects the highest death-rate was 40·91 per 1,000 registered among Hindus, Muhammadans follow with 37·95, then "Other Classes" 33·51, and, lastly, Christians 11·58.

The monthly mortality, which had been above the average until May, fell to a minimum in June, when it was below the average of the previous ten years; there was a slight rise in July, and a further rise in August and September, until October, when the mortality mounted upwards; it fell slightly in November and considerably in December.

Among male infants the death-rate was 262·97 per 1,000, and among females 255·10; among boys and girls between one year and five years of age the millesimal rates were, respectively, 73·64 and 72·78. At all age-periods, save that between 15 and 20, the male death-rates were the higher, the excess rising generally with advancing age; and the average male death-rate was 42·06 per 1,000 against 38·73 among females.

Punjab.—No alteration in the method in force for the registration of vital statistics was made during the year, and the comparatively high standard of efficiency attained in the Punjab in recent years was maintained, in the opinion of the provincial Sanitary Commissioner, mainly by the inspection of registers. These inspections are carried on by tahsildars, vaccinators and special divisional inspectors of registration. The work done by tahsildars seems to be of little value, so far as the detection of omissions is concerned at any rate; the inspection by vaccinators is fairly effective; and the work of the special inspectors seems to be very good. The number of *chowkidars* fined for neglect was 488—not a very large number, but enormous in comparison with the 59, which was the total number of persons fined in the municipal towns for breach of the bye-law regarding registration.

The number of births registered during the year was 874,623 against 884,692 in 1896. Although the birth-rate of the year, 42·6 per 1,000, was slightly lower than the rate recorded in the previous year, when it was 43·04, it is considerably higher than the quinquennial mean of 40·8. The highest district birth-rates were 57·5 and 53·2 recorded in Jhang and Gujranwala, where the population has largely increased since the census of 1891 on account of the opening of the Chenab Irrigation Canal. The next highest rate was 49·6, recorded in Karnal, and from this the rates fall until 31·4 per 1,000 is reached in Hazara, 30·3 in Kangra, 30·5 in Peshawar and 19·3 in Simla. Hazara and Peshawar are frontier districts in which probably one-third of the births are not registered, the former shows a falling off in the improvement secured in the last few years, the latter is gradually improving. Kangra and Simla are both hill districts; in the latter, which is the only district in which the number of deaths exceed the births, there is a great excess of males in the population, a condition which obtains in Kangra also to a slight extent. As compared with 1896 the districts of Hissar, Jhelum and Gujrat show a falling off, very marked in the case of Hissar, due to emigration from them on account of famine.

In the province generally there were 110·5 male infants born for every 100 female infants, the percentage ranging from 141·3 in Peshawar to 105·3 in Kangra. It is curious that the extremes should both be districts in which registration is apparently most defective. Admitting that the concealment of female births is general throughout the province, it might be expected that the majority of omissions detected in the birth and death registers would refer to females. But this is not the case. Vaccinators and inspectors alike found the greater proportion of omissions referred to males; although the special inspectors found a higher proportion of omissions in registering the deaths of females. No satisfactory explanation of the excessive proportion of male births registered is given, and criticism in the light of the proportion of omissions detected in the registers is of little value, since it is not explained what exactly constitutes an omission.

The year was unusually healthy, and the number of deaths recorded fell from 648,099 to 638,227. The death-rate was 31·05 per 1,000 against 31·53 in 1896, and a quinquennial average of 34·99. There was a notable decrease in the mortality from small-pox, which was epidemic in 1896, but this was almost exactly balanced by an increased mortality under "Fevers." There was a smaller number of deaths from cholera and from "Other causes," but dysentery and diarrhœa were more fatal. The highest district death-rates were 50·2, 45·3 and 44·3 recorded, respectively, in Dera Ismail Khan, Hissar and Muzaffargarh. In Dera Ismail Khan and Muzaffargarh, as well as in Bannu, Karnal and Jhang, the mortality from fever in the autumn was very high. In Hissar there was scarcity, and although only two deaths from actual starvation were reported, there was exceptional mortality among young children and old persons. The lowest district death-rates were registered in Peshawar, 22·9 per 1,000, and in Simla and Gujrat, 21·9 respectively.

The average mortality in rural areas was 30·68, as compared with 34·44 per 1,000 in the towns, where cholera, dysentery and diarrhœa, and diseases classed under the heading "Other causes," were more fatal than in the country. The highest urban death-rates were 96·12 and 78·36 per 1,000, recorded in Khairpur and Karor, small towns in Muzaffargarn and Dera Ismail Khan, where fevers were exceptionally prevalent. The town of Dera Ismail Khan, which comes next with 75·28, is very ill-drained and fevers were exceedingly fatal, The lowest death-rates were recorded in the Miani 15·79, Montgomery 15·12 and Abbottabad 12·93.

The Muhammadan death-rate was 31·24, and the Hindu 30·78, the relative positions of the two sects being reversed since last year. Native Christians were reported to have died at the rate of 17·25, and "Other Classes" at the rate of 114·55. It seems clear that registration is neglected among the native Christian community, and that most of the unknown dead are returned among "Other Classes"; whenever the population of the former was considerable, the death-rates were very low; and in Delhi the number of deaths registered among "Other Classes" was more than six times the local census population of that community. By far the highest death-rates were registered in November and October when fever was rife; and the lowest rate was registered in February followed fairly closely by April and March.

Male infants died at the rate of 223·02 per 1,000, and females at the rate of 228·02. Boys and girls below five years of age died, respectively, at the rates of 58·42 and 66·76, and at all age-periods, except those between 40 and 60, the female death-rates were the higher, the total male death-rates having been 29·6 as compared with 32·7 among females.

Central Provinces.—The year 1897 was one of extraordinary misery in the Central Provinces. The acute distress which, in 1896, succeeded the localized scarcity of 1894 and 1895, was followed by severe famine involving nearly every district in the province. In January there were 217,762 persons receiving relief, and the number rose in May to a maximum of 691,890; in October, after a defective but well-distributed monsoon rainfall, when the new crops provided cheap food, the numbers began to fall, and, in November, those receiving aid from Government numbered only 151,446.

The number of births registered was 254,973, as compared with 301,427 in 1896; and the birth-rate, 26·83 per 1,000, was the lowest on record—4·9 per 1,000 less than in 1896, and nearly 10 per 1,000 less than the low average in the preceding five years. In 1896 the district birth-rates were generally very low, but in 1897 they were still lower in 14 districts, and the six remaining, Chhindwara, Nimar, Nagpur, Wardha, Chanda and Sambalpur, with the exception perhaps of the first named, escaped more or less from the worst effects of famine. In only one district, Sambalpur, where there had been failure of harvests and the numbers on relief never exceeded ·035 per 1,000 of the population, were births more numerous than deaths; in every other district the death-rates were higher than the birth-rates. In Burhanpur and Chanda the excess of deaths over births was comparatively small, 3·59 and 6·93 per 1,000, but in the other districts the figures ranged from 15·21 in Nagpur and 15·39 in Chhindwara to 80·26 in Murwara and 82·00 in Mandla. Among the districts the highest birth-rates were noted in Nimar, 46·30 per 1,000, Burhanpur, 40·19, Wardha, 39·83, and Sambalpur, 39·24; in only four other districts, Chhindwara, Nagpur, Chanda and Betul, were the rates over 30 per 1,000. In six districts the birth-rates were less than 20 per 1,000, namely, Narsinghpur 19·72, Saugor 17·52, Murwara 16·79, Damoh 16·77, Mandla 16·36, and Balaghat 16·23. It is remarkable that in all these districts the percentage of male to female births was higher than the provincial average, in some cases very much so; in Saugor the percentage was 117·34, in Mandla 113·58, in Narsinghpur 113·16, in Damoh 111·26, in Murwara 108·53, and in Balaghat 108·09. In four other districts percentages above the average were recorded—in Nimar (109·59) and Wardha (108·64), where the birth-rates were fairly high, and Jubbulpur (108·48) and Bilaspur (109·60), where they were low. The smallest percentage noted in any district was 105·01 in Chhindwara.

In the report for 1896 we had to record a death-rate which, except in 1878, had never been nearly equalled in the Central Provinces; in 1897 the death-rate was more than 20 per 1,000 higher than in 1896. The total number of deaths registered was 658,822, as compared with 468,469 in the previous year, and the death-rate was 69·34 per 1,000 as compared with a quinquennial mean of 37·02. The effects of famine are clearly written in the mortuary register of every district save Sambalpur. In every district the death-rate was higher than the average of the preceding five years, and in only two were the rates lower than they were in 1896. These two exceptions were Damoh, where the enormous death-rate of 88·28 per 1,000 was recorded in 1896, and Sambalpur, where, as has been

already stated, distress was limited. Cholera was more than twice as fatal as is ordinarily the case ; dysentery and diarrhœa caused more than four times the high average death-rate of recent years ; and fevers, to which 59 per cent. of the total mortality was ascribed, caused a death-rate of 40·98 per 1,000, as compared with a quinquennial mean of 23·13. In 171 of the 233 circles of registration the death-rates were in excess of 50 per 1,000, including forty-five in which there were upwards of 90. In only one circle was the rate lower than 25, although in the other five they were less than 30. Among the districts the highest death-rates were recorded in Mandla, 98·36, Murwara, 97·05, and Bilaspur, 95·54 ; the lowest were recorded in Burhanpur, 43·78, Chanda, 41·58, and Sambalpur, 30·22. High as was the average death-rate in rural areas, 68·20 per 1,000, it was far exceeded in the towns where 81·57 per 1,000 of the census population died. In many of the towns, of course, the rates were raised by the inclusion of the deaths of starving wanderers from the surrounding country in search of food, who died in the poor houses, orphanages and other temporary establishments where the succour of the helpless was attempted. The effect of this migration is well seen in the difference in the proportions of the various causes of death in rural areas and in town circles of registration, although allowance must be made for the less faulty classification of disease in the latter. The millesimal death-rate from dysentery and diarrhœa in the country was 6·99, while it was 25·16 in the towns. Deaths from "All other causes" showed an excess of 9·00 per 1,000 in the towns, as compared with the country ; and, as might be expected, small-pox and injuries caused more deaths in the former. Under the heading of fevers the rural mortality was 12·92 per 1,000 higher than the urban ; and to cholera was attributed 6·11 deaths per 1,000 in the country, against 4·87 in the towns. The highest death-rate in any town was 510·83 per 1,000 in the small town of Mungeli in the district of Bilaspur ; this was followed by 313·21 in Murwara, the only town in the district of the same name. In Burha (306·73), Bilaspur (297·34), Mandla (238·87), Seoni (203·99), Khurai (264·19), Rehli (207·85), Damoh (202·59), Sehora (207·31) and Lakhnadon (285·36), rates in excess of 200 per 1,000 were recorded. The death-rate exceeded the birth-rate in every municipal town except Pandhurna in Chhindwara.

The lowest death-rate was 52·61 among Muhammadans, followed by 59·72 among Hindus. Among "Other Classes," comprising the savage or half savage aboriginal tribes, the rate was 126·23 per 1,000. These poor people are largely dependent on the produce of their jungles, so that they speedily feel the effect of unfavourable seasons, and being timid and unwilling to undertake organized work at the best of times, are peculiarly difficult to assist effectively in times of famine.

Every month of the year levied a larger tribute of mortality than in 1896. The death-rate fell to a minimum of 3·51 per 1,000 in February, and rose rapidly after March to 7·54 in June ; after a slight fall in July, it rose in August, to a maximum of 8·62 in September; it fell slightly in October and rapidly in November to a millesimal rate of 3·91 in December.

Infantile mortality was enormous, reaching 403·00 and 356·11 per 1,000 among males and females respectively. Boys and girls over one year and under five years of age died at the rates of 79·64 and 63·78 per 1,000. At all ages the male death-rates were the higher, the average rates for males and females having been, respectively, 77·02 and 61·67 per 1,000.

It is a feature of the mortality in the Central Provinces that the male death-rates are higher at all ages than the female rates ; but while there is generally an approximation to equality on account of a comparative rise in female mortality at the child-bearing ages, no such rise was perceptible in 1897.

No change in the systems in force for the collection of vital statistics was made during the year ; but, as evidenced by a great increase in the numbers against whom proceedings were instituted under the Act, more attention is being given to the matter in municipal towns.

Berar.—There was again some improvement in registration in Berar, due probably to the inspection of registers, of which a larger number were examined than in the previous year. Registration appears to be most defective in Basim and in Wun, but improvement may be looked for, as there was a considerable increase in the number of registers examined in the former district, and a great increase in the latter. In towns registration is still defective, but is improving, except in Ellichpur and Khamgaon, where greater attention on the part of the municipal authorities is required.

The number of births registered was 113,364, as compared with 109,013 in 1896, and the birth-rate, 39·7, was 1·4 per 1,000 higher than in that year, and 2·1 in excess of the

quinquennial mean. The highest district rate was 40·4 recorded in Akola, and the lowest, excepting 37·0 in Basim, where registration is bad, 39·9 in Buldana. The average birth-rate in rural areas was 39·8, the provincial average being lowered by the rates in towns, of which the average was 38·8. Some of the urban rates were high, 51·3 in Akot, 47·0 in Wadegaon, both in the Akola district, and 47·0 in Pusad in Basim. None of the rates were very low, 31·0 per 1,000 in Umarkhed, and 29·6 and 26·7 registered, respectively, in Ellichpur Civil Station and Ellichpur City, being the lowest.

The percentage of male to female births was 106·7, the extreme variations being 146·6 in Barsi Takli and 84·7 in Digras, both small towns in which in other respects normal rates were registered.

There was a remarkable variation in the monthly birth-rates. Ordinarily, the largest numbers of births occur in August, September and October; in 1897 the largest numbers were recorded in February, March and July. The numbers of births in every month up to the end of July were in excess of the decennial mean; in August the numbers fell and remained below it, the falling off in December being 1,690 less than the decennial mean, and 3,651 less than in December 1896. Lieutenant-Colonel Little explains the falling off as due to the effects of famine, which began to be felt in October 1896, diminishing fecundity; and it was observed that women driven to relief centres were rarely pregnant. This, however, does not explain the excess of births in the first part of the year.

The total number of deaths recorded was 150,222, and the death-rate, except in 1878, when it was 81·5 per 1,000, was the highest on record, 52·6 as compared with 43·8 in 1896, and 39·4, the average of the preceding five years. The highest district rate was 61·1 per 1,000 in Amraoti, where large numbers of starving immigrants, coming from the Central Provinces in search of work and food, died. In the other districts the rates ranged from 55·5 per 1,000 in Akola to 42·1 in Wun. The rural death-rate was 51·9, slightly below the provincial average, while the urban rate, 57·4, was considerably above it. In the towns the rates were raised by the influx to them of the starving poor to relief works; the same cause, of course, lowered the rural rates. The highest urban rates were 92·2 per 1,000 in Morsi, where besides cholera, fever and dysentery and diarrhœa were exceptionally fatal, 91·3 in Pusad, and 86·0 in Talegaon, in both of which cholera was severe.

The Muhammadan death-rate was 45·8, as compared with 51·9 among Hindus, among whom the outcaste tribes are very poor. Christians died at the rate of 44·5, and "Other Classes," mainly made up of the timid and impoverished aboriginal tribes who suffered severely from famine, at the rate of 82·7 per 1,000.

The lowest death-rates were recorded in February and March, and the highest in August and September, when the wet cold weather of the monsoon proved fatal to many of those enfeebled by the effects of famine.

There was a great increase in mortality at the extremes of life. Infants, male and female, died at the rates of 325·9 and 360·9 per 1,000, as compared with 273 and 233 in 1896; boys and girls under five died, respectively, at the rates of 101·1 and 91·0, as compared with 97·5 and 81·5; while old men and women, aged 60 and upwards, died at the rates of 150·3 and 127·2 respectively, as compared with 107·4 and 96·6 in the previous year. At all age-periods, save those between 10 and 30, the male rates were the higher, the average being 55·3 per 1,000 for male and 49·9 for females.

Madras.—There was no alteration made during 1897 in the method in use in Madras for the collection of vital statistics, which has been described in former reports. A suggestion was made by the Deputy Director of Agriculture that birth registers should be used in rural areas to check vaccination. The adoption of this check was, it is stated, suggested by Lieutenant-Colonel King in 1891, and has been in successful operation in municipal towns in Madras since 1895.

The total number of births recorded during the year fell from 979,981 in 1896 to 935,845, and the birth-rate from 29·9 to 28·7, as compared with 27·8 per 1,000 the quinquennial mean. Although registration continues to be defective, the falling off in the number of births, which was recorded in fifteen districts, is believed by the Sanitary Commissioner to be due to an actual decrease in the number of children born, because of the large number of marriages postponed as a result of the native prophecy that a cycle of famine and pestilence was about to begin. The highest district rates were those recorded in Madras (Town) 41·6 per 1,000, Chingleput 37·1, and Kistna 34·9; and the lowest in Godavari 25·4, Ganjam 23·9, and Malabar 20·8. The average rural birth-rate was 28·4 per 1,000, as compared with 32·7 in the towns.

There were 104 boys born against every 100 girls, the district percentages ranging from 109·2 in Ganjam to 98·7 in the Nilgiris. In the former district registration is

peculiarly defective; and in the latter the population is comparatively small, so that variations from year to year must be expected—in 1896 the percentage of boys born to girls in the Nilgiris was 117·0.

The millesimal birth-rate fell from 2·3 per 1,000 in January to the minimum of 2 in February; it gradually rose in July to 2·7, fell slightly in August and September to rise again to 2·7 in October, and then declined rapidly until the end of the year.

The number of deaths registered was 827,525, as compared with 675,787 in 1896, and the death-rate rose from 20·6 per 1,000 in that year to 25·4, or 5 per 1,000 above the quinquennial mean. The death-rate was higher than that of the preceding year, and in excess of the mean in fifteen districts; in seven of these, Anantapur, Bellary, Cuddapah, Ganjam, Godavari, Kurnool and Vizagapatam, the presence of famine was officially recognized, and in two, Malabar and South Canara, the pinch of scarcity was felt. The highest district rates were 50·1 recorded in Ganjam, where, besides cholera, small-pox was exceedingly prevalent, 35·8 in Madras (Town), and 31·6 in Vizagapatam. The lowest district rates were 20·1, 19·5 and 19·3 recorded, respectively, in Coimbatore, Nellore and Salem. In rural areas the average death-rate was only 24·8, as compared with 31·9 in the towns. Among the latter, the highest rates were recorded in Cannanore, 56·8 per 1,000, where the high rate was largely due to great mortality (28·5 per 1,000) from cholera; 53·2 in Kurnool due to fevers and "Other causes"; and 50·5 in Calicut, where cholera was rife. The lowest urban rates were 9·8, 9·7 and 7·3 registered, respectively, in Shendamangalam, Samalkot and Ambur.

The Muhammadan death-rate, 27·3 per 1,000, was the highest, followed by that of the Hindus, who constitute about 90 per cent. of the population, with 25·5; Native Christians died at the rate of 17·9, and "Other Classes" at the rate of 12·5.

The smallest numbers of deaths were registered in February, March and April in the order given; and the largest numbers in August and December.

The death-rates of infants were 148·9 and 124·2 per 1,000 of males and females, respectively, a slight reduction as compared with 1896 in the case of males, due, no doubt, to the decrease in the number of infants born, for there was a notable increase in the mortality at all other age-periods, the numbers of boys and girls under five who died rising from 24·9 and 22·8 per 1,000, respectively, to 30·2 and 28·3. At all age-periods, save those from 15 to 29, the male death-rates were the higher, the average being 26·4 per 1,000 for males, against 24·4 for females. In the death-rates of the sexes in the age-periods 20 to 29 and 30 to 39 there is a curious departure from the normal proportions as determined by the death-rates of the past five years. In the earlier age-period, while the male rate is slightly increased, in harmony with the general rise in mortality, there is a disproportionate increase in the female rate. In the later age-period conditions were reversed, the female death-rate is normal, and that of males greatly increased.

Coorg.—The total number of births recorded in Coorg was 3,503, a decrease of no less than 1,103 as compared with the number recorded in 1896; and the birth-rate fell from 26·62 in that year to 20·24, against a quinquennial average of 24·18. Registration is admittedly defective, and the excess of males among the population is nearly 20 per cent., but as there is no reason to believe that the registration of vital statistics became more defective during the year, or that the female population decreased, it must be concluded that there was a remarkable falling off in the number of children born. The rates in the various districts varied from 15·36 per 1,000 in Yedenalknad, where the disparity in the numbers of the sexes is greatest, to 26·12 in Nanjarajpatna, where it is least. The percentage of male to female births was 100·74, as compared with 97·68 in 1896, and ranged from 108·14 in Merkara Taluk to 93·63 in Kiggatnad.

The year was a remarkably unhealthy one, and a severe form of fever, described as malarial, attacked rich and poor alike and proved exceedingly fatal. The number of deaths registered was 8,658, by far the largest number ever recorded, and 4,084 more than in 1896. The death-rate was 50·03 per 1,000, against 26·43 in the previous year, and 27·19 the quinquennial mean. The death-rate was higher than the birth-rate in every taluk, and ranged from 34·45 in Kiggatnad to 66·47 in Padinalknad. In rural areas the death-rate rose from 25·84 in 1896 to 48·84 per 1,000, as compared with a ratio of 62·15 in the five towns, where the average rate in 1896 was 32·43. In the towns many coolies from Malabar, South Canara and Mysore died in hospital, so that the urban death-rate is exaggerated.

Among Hindus, who form the bulk of the population, the millesimal death-rate was 48·84; among Muhammadans it was 49·82; and among the small population of "Other

Classes," 103·53. The number of deaths fell to a minimum in February, gradually rose to a maximum in July, and then declined, with the exception of a slight rise in October, to the end of the year.

The death-rate among infants was 359·85 per 1,000 among males, and 331·37 per 1,000 among females, as compared with 260·89 and 230·87, respectively, in 1896. There was a great rise in the death-rates of children under five, from 34·09 and 30·28 per 1,000 for boys and girls, respectively, in 1896 to 77·06 and 78·41 in 1897. The female death-rate was 51·94, or 3·45 higher than the male, and only in infancy and in the age-periods 5 to 10 and 40 to 50 were the male rates the higher.

Bombay.—The total number of births registered in the Presidency of Bombay, including Sind, was 629,693, as compared with 691,847 in the previous year; and the birth-rate fell from 36·76 per 1,000 in 1896 to 33·46, or 2·05 per 1,000 below the quinquennial average. The birth-rates were lower than in 1896 in all the registration districts, and in only three of the 24 collectorates, Thana, Thar and Parkar, and Upper Sind Frontier were they higher. In Thana the total rate was considerably higher than the average of the previous five years, while the urban rate was lower than in 1896, which suggests that the increase in the rural areas may be due to immigration of women from plague-stricken centres. The highest district rates were 44·11, 42·39 and 41·73 per 1,000 recorded, respectively, in Khandesh, Broach and Nasik; the lowest were 26·37 in Karachi, 18·05 in Hyderabad, and 11·29 in Bombay City.

The rural birth-rate was 34·66 against 24·85 in the towns. Among the latter, the highest rates were recorded in Vengurla 56·22, Sangamner 55·68 and Kapadvanj 54·17; while the lowest rates were registered in Thana 14·61, Bombay 11·29 and Poona 10·44, in all of which plague was severely epidemic.

The percentage of male to female births was 108·42, ranging from 135·0 in Hyderabad to 102·49 in Panch Mahals.

The total number of deaths registered was 749,916, as compared with 596,472 in the previous year, and the death-rate was 39·84 per 1,000, as compared with 31·69 in 1896, and 30·45 the quinquennial average. In accounting for the rise in the death-rate two factors must be taken into account—the presence of famine and the epidemic of plague. As a result of the famine, cholera was more rife than usual, and caused 3·03 deaths per 1,000 of the population, as compared with a quinquennial average of 1·48, and dysentery and diarrhœa were exceedingly fatal, giving rise to a death-rate of 4·57 per 1,000, against an average in the preceding five years of 1·85. The epidemic of plague not only occasioned a recorded death-rate of 2·49 per 1,000, but many plague deaths were registered under some other heading, and the special exertions made to detect cases stimulated the registration of deaths from all causes. It would be useful as well as interesting to ascertain the actual death-rate from plague, but defects in registration and the peculiar conditions of the year render this difficult, if not impossible. The registered excess of the total mortality in 1897 over the mean of the preceding five years was 9·39 per 1,000. From this must be deducted the excess attributed to cholera (1·55), dysentery and diarrhœa (2·72), small-pox (·01) and injuries (·05), which aggregate 4·33 per 1,000. The balance, 5·06, must be divided among "Fevers" and "All other causes." The fever death-rate in 1897, which includes deaths from plague, was 24·05, or 2·49 per 1,000 more than the quinquennial average of 21·56; and 2·49 is very curiously exactly the recorded millesimal death-rate from plague. The mortality registered in 1897 under "Other causes" in excess of the five years' mean was 2·58. In other provinces where there was scarcity but no plague fever death-rates have been raised, so it may be concluded that had there been no famine in Bombay the fever death-rate would not have been much higher than normal in spite of the plague; and, indeed, meteorological conditions favoured a low fever death-rate. If to plague is assigned all the excess mortality under "Fevers" (2·49) and "Other causes" (2·58), the actual death-rate from plague would be over 5 per 1,000, which would mean that rather less than half the actual number of deaths from plague were recorded as due to that disease. The highest district death-rates were 58·89 per 1,000 in Bombay City, 56·95 in Poona, 55·64 in Nasik and 54·92 in Satara, in all of which plague was virulently epidemic; the lowest were 21·11 per 1,000 in Panch Mahals—one of the two districts where no plague death was registered—19·86 in Thar and Parkar, and 15·92 in Hyderabad. In Thar and Parkar there were only two deaths attributed to plague, but there were 499 in Hyderabad, both are in Sind, where registration is defective.

The rural death-rate was 37·49 per 1,000, as compared with 56·72 in the towns. Among the latter, the highest death-rates were 148·78, 100·97 and 99·73 per 1,000, registered, respectively, in Karad, Sholapur and Nasik, due in the first two cases to high rates under

fever, and in Nasik to a comparatively high fever rate and the enormous rate of 22·66 per 1,000 under dysentery and diarrhœa. The lowest urban death-rates were 26·14 in Kumta, 21·77 in Karwar, both in Kanara, a district in which plague did not appear, and 10·63 in Ahmedabad Cantonment.

Among the various sects, the Hindus had the highest death-rate, 42·64, then the Christians, 37·74, Parsis followed 32·56, and then Muhammadans with 30·14. The considerable population, 224,773, of "Other Classes," including Buddhists, Jews, Sikhs, and "unspecified," died at the rate of only 9·95 per 1,000. It is obvious, from an examination of Annual Form V., that this is absurdly wrong, and is due to deaths among "Other Classes" being credited to some other section, *e.g.*, in the district of Broach the population of "Other Classes" is 17,828, and in Panch Mahals it is 11,086, but no death was registered among them; while in the same districts, three deaths occurred among an aggregate Christian population of 136.

The monthly death-rate fell to a minimum in February, and then rose gradually to a maximum in August, fell rapidly in September, and afterwards gradually until the end of the year.

Infants died at the rates of 212·77 males and 188·43 females per 1,000; and boys and girls between the ages of one year and five years at the rates of 64·18 and 60·77 per 1,000. At all ages, save from 5 to 19, the death-rates of males were higher than those of females, the differences increasing with advancing years, the average male death-rate being 40·68 as compared with 38·95 among females.

Burma.—Registration is in force throughout Lower Burma, except in the Northern Arakan and Salween districts, and in parts of the Akyab, Bassein, Thayetmyo and Toungoo districts; the census population concerned comprising 2,388,758 males and 2,126,015 females. In Upper Burma registration, in 1897, was confined to the populations of the towns of Mandalay, Myingyan, Pyinmana and Yamethin, aggregating 227,310 souls; but the registration of births and deaths is about to be gradually introduced into other towns, and the registration of deaths into all the more populous and civilized areas. The system in force in Lower Burma, whereby registration is carried out in municipalities and towns by special paid registrars or ward headmen, in villages by headmen appointed under the Lower Burma Village Act, and in rural areas by the police, continued in force; but amended rules to fix responsibility and simplify procedure were issued in April 1897.

The total number of births recorded during the year was 143,659, about 2,000 fewer than in the preceding year, and the birth-rate was 31·82 per 1,000, against 32·27 in 1896. There seems to be no reason to fear that the improvement in the registration of vital statistics which has been brought about in recent years is not to be maintained, for although lower than that of 1896, the birth-rate of 1897 is higher than that recorded in any previous year, and is 3·86 per 1,000 in advance of the quinquennial mean. The highest district birth-rates were 40·97, 40·43 and 38·83 per 1,000 recorded, respectively, in Sandoway, Pegu and Myaungmya, and the lowest 27·18, 26·52 and 17·61 in Amherst, Thâton and Rangoon Town district. In view of the low district rate recorded in the Thâton district, it is remarkable that in the town of the same name the birth-rate should be the second highest, 38·21 per 1,000, being preceded only by the town of Kawkareik, where the birth-rate was 47·79.

In the province as a whole 108 male children were born for every 100 female children, the rates varying from 116 in Rangoon Town district to 104 in Sandoway. Among the various communities there was great variation in the percentage of males born as compared with females, 115 among Christians, 109 among Hindus, 108 among Burmese and among "Other Classes," and 104 among Muhammadans. These variations seem to have no relation to the birth-rates, which ranged from 33·47 among the Burmese to 21·32 among Christians, and 8·57 per 1,000 among Hindus.

In the province as a whole the largest number of births was recorded in December, and the least in April.

The total number of deaths registered was 118,570, against 106,687 in 1896, and the death-rate, which was the highest on record, was 26·26 per 1,000 as compared with 23·63 in the previous year, and 22·27 the quinquennial mean. In the districts the highest rates were 38·33 recorded in Rangoon Town district, 36·73 in Pegu, and 32·61 in Myaungmya; while the lowest were 18·94 recorded in Thâton, 18·11 in Tavoy, and 14·44 in Mergui. In rural areas the average death-rate was 25·33 against 32·34 in the towns, where the rates ranged from 43·89 and 38·24 per 1,000 in Zigon and Myaungmya, respectively, to 17·87 in Shwedaung, 17·76 in Mergui, and 15·87 in Thônzé.

Of the sects, the Hindus had the highest death-rate, 31·51 per 1,000, and the Christians the lowest, 15·21, "Other Classes" occupying an intermediate position with 23·38 ; the rate among the Burmese was 26·68, and among Muhammadans 20·85.

The lowest mortality was recorded in February, the differences in the other five months of the first half of the year being slight; there was a sudden rise in the death-rate in July, when the largest number of deaths was registered, and a slight gradual fall until December, when the number of deaths again began to rise.

Among male infants the death-rate per 1,000 living was 269·24 as compared with 188·24 among females, both a considerable advance on the rates in 1896 ; a similar advance in the mortality was recorded among boys and girls between one year and five years of age, the rates having been, respectively, 35·66 and 30·53, against 33·60 and 28·57 in the previous year. The average death-rate among males was 27·76 against 24·58 among females, and at every age-period, except from 30 to 40, the male rates were the higher.

History of Chief Diseases.

Cholera.

There is nothing new to record bearing upon the microbial origin of cholera ; but allusion may be made to the connection established by Dr. E. Klein between the bacillus enteritidis sporogenes discovered and named by him in 1895* and some cases of cholera *nostras*. The bacillus is an anaërobic microbe, probably derived primarily from excrement and widely distributed in nature. It is particularly abundant and virulent in animal excreta and substances contaminated therewith, so that Dr. Klein has come to look upon the discovery of its presence in water as a more trustworthy criterion of direct fæcal pollution than the presence merely of bacillus coli.† Milk forms an exceedingly favourable medium for the culture of bacillus enteritidis sporogenes ; and, although the virulency of the microbe varies, the spores are frequently to be found in milk exposed for sale in London, even after the milk has been subjected to the ordinary trade process of "sterilization." Dr. Klein took a sample from a bottle of "pure sterilized milk," heated it to 80° C. (176° F.) for 15 minutes, and then incubated it anaërobically at the body temperature, when it yielded a pure culture of the virulent bacillus. Dr. Klein states, however, that the spores are destroyed by direct boiling in from three to five minutes.

The experience of the year teaches little that is new in the prevention and treatment of epidemic outbreaks of cholera in India. The old lessons are repeated ; cholera cannot be prevented by any single precaution, and no possible precaution should be omitted ; when the disease appears in epidemic form, prompt movement, intelligently carried out, is the most effective check.

The experience of the North-Western Provinces is encouraging, for it serves to show that even in a year of famine, well-devised measures for preventing the occurrence and checking the continuance of epidemics, carried out on a carefully organized plan, will not only save the lives of many relief workers, but will prevent their becoming a source of danger to the general public.

The two experiments in cholera prophylaxis by the disinfection of water-supplies and anti-cholera inoculation, to which allusion was made in this Report for 1896, were continued during 1897.

The disinfection of wells by means of permanganate of potash was practised systematically in most provinces, and the results are generally considered to have been satisfactory, although, in view of the fact that it is impossible to say that the disease would not have ceased in any case, and the difficulty in disinfecting every source of water-supply, it is very hard to obtain evidence of a conclusive character. The only circumstantial account of the effect of the measure is to be found in the Bengal Sanitary Report. The Civil Surgeon of Lohardaga carefully recorded the result of the disinfection of four wells in the town of Ranchi. In each case after the disinfection of the well only one case of cholera occurred among the people using the water.

In the North-Western Provinces and Oudh permanganate of potash was used to purify the wells in relief camps, not only in the presence of cholera, but whenever there was any

---

† Report of the Medical Officer, 1897–98, p. xx. and Appendix B–1.

doubt regarding the quality of the water. The Sanitary Commissioner thinks there can be no doubt about the utility of the proceeding, but states that experience shows that if it is to be effective it must be practised every three or four days.

In the Central Provinces the disinfection of water-supplies was generally used, and most of the Civil Surgeons considered it beneficial, although there is some divergence of opinion among them. The Civil Surgeon of Mandla, where cholera was exceedingly severe, states that, "the use of the permanganate of potash never failed to control and "quickly stamp out the most virulent epidemic." On the other hand, the Civil Surgeon of Bilaspur states that wells were disinfected, "but with no apparent effect on the course "of the disease," which he suggests may be explained by the impossibility of disinfecting the great number of sources of supply. The Sanitary Commissioner, in summing up the evidence, writes, "The application in fact of permanganate of potassium to ordinary "unprotected water-supplies does not, it may be definitely stated, much or materially "diminish the risk of cholera infection in epidemic times."

In Berar the general opinion was that the use of permanganate had a beneficial effect, but it is pointed out that the number of wells in a Berar village or town renders systematic disinfection almost impossible.

In Madras the purification of water-supplies, when small, by permanganate of potassium, and when large, by lime or alum, was freely practised. Although the people sometimes objected to the red colour produced by the permanganate, in most districts the people as well as the medical officers regard its use with favour.

Anti-cholera inoculation.—Preventive inoculation against cholera was carried on in Bengal throughout the year, and 10,950 persons were operated on, mostly coolies on their way to the tea districts of Assam and Cachar. No complete statistics regarding the efficacy of the inoculations have been obtained, but such facts as were recorded are in favour of inoculation. Cholera was extraordinarily prevalent in 1897 among the coolies on their way to the labour districts in Assam and Cachar, and it is possible to compare roughly the mortality among the inoculated and uninoculated among the general body of immigrants on their way to the former. Confining the calculations to deaths which occurred between the ports of embarkation and the tea gardens, it appears that the general cholera death-rate was 16·7 per 1,000, and that the death-rate among inoculated coolies was 4·9 per 1,000. There are probably other circumstances besides inoculation to be taken into account; but it seems likely that, in the future, the data will be more complete, for the Chief Commissioner of Assam has prescribed a half-yearly return to be prepared by managers of tea gardens, in which will be shown the deaths from cholera on the gardens among uninoculated persons and among inoculated persons, (1) within six months, (2) between six and twelve months, (3) between one and two years, and (4) after two years from the date of inoculation.

It was stated that a large number of the men of the Shropshire Regiment, among whom there was a very severe outbreak of cholera at Sitapur in September, had been inoculated by M. Haffkine at Fort William in 1896. An examination of the medical history sheets, however, showed that if more had been inoculated, the operation was recorded in 27 cases only. The number of men at Sitapur when the epidemic began was 435; of these 65 were attacked and 41 died of cholera. Among the 27 inoculated men four were attacked and two died. So that among the uninoculated the percentage attacked was 14·9 and the case-mortality about 63 per cent., while among the inoculated the percentage attacked was 14·8 and the case-mortality 50 per cent.

Anti-cholera inoculation was carried out during the epidemics in the jails at Hazaribagh and Ranchi, but although none of the inoculated were attacked, it does not seem that anything can be proved regarding the protective effect of the proceeding. The medical officer of the jail at Ranchi found that of 335 inoculated 31·3 per cent. gained weight after the operation, 45·3 lost weight, and 23·3 neither lost nor gained.

The total number of deaths registered as due to cholera throughout India and Burma in 1897 was 555,035, as compared with 471,779 in 1896. During the last twenty years the cholera mortality of 1897 has been exceeded on only three occasions; in 1877, when the number of deaths was 635,977, including the enormous total of 357,430 deaths in Madras; in 1891, when the deaths numbered 582,081; and in 1892, when the total reached 727,493. Deaths from cholera were less numerous in 1897 than in the preceding year in Bengal, the North-Western Provinces and Oudh, the Punjab, Berar, Rajputana and Central India; in all the other provinces deaths were more numerous than in 1896; and in Madras, Bombay, the Central Provinces and Assam the mortality was quite exceptional.

The following statement shows the total numbers of deaths ascribed to cholera in every province in India in each year from 1877 onwards :—

Statement showing the deaths from Cholera in the different Provinces in India from 1877 *to* 1897.

YEAR.	Bengal.*	Assam.	N.-W.P. and Oudh.	Punjab.	Central Provinces.	Berar.	Rajputana.	Central India.	Bombay.	Hyderabad.	Madras.	Mysore.	Coorg.	Lower Burma.	Ajmere-Merwara.

* Excluding Calcutta from 1877 to 1892. † Including four deaths, the monthly distribution of which is not known.
‡ Statistics not available.

In the following statement the season distribution of the disease in the different provinces is exhibited. It will be observed that in the country generally, August, June and July, in the order given, were the months of greatest prevalence ; while, as in 1896, the mortality was least in February, January and November :—

Statement showing the Deaths from Cholera registered in the different Provinces by Months during the year 1897.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.	RATIO OF DEATHS PER 1,000 OF POPULATION. 1897.	1896.

Ajmere-Merwara ...	·04	·98	·11	·01	·54	·21	·19	August.

Bengal.—The total number of deaths registered as due to cholera in Bengal was 196,247. The death-rate from this disease was 2·76 per 1,000, much less than the death-rate of 1896, which was 3·19, and ·13 below the average of the previous five years. As usual, every district in the province suffered, and in most of the districts cholera was present throughout the year. In spite of the lower death-rate the percentage of villages attacked was higher than in 1896—13·26 as compared with 12·23. In 26 districts the cholera death-rates were below the average and in 20 above it. Cholera was far more prevalent than usual in all the districts of Chota Nagpur, and much less prevalent than usual in the districts of the Patna Division. The highest district death-rates were 9·57 per 1,000 recorded in Puri, 8·35 in Chittagong, and 8·02 in Lohardaga. Puri always suffers more or less severely from cholera. Great numbers of pilgrims pass through it along the pilgrim road on their way to attend religious festivals, and these people are, from the conditions of their pilgrimage, peculiarly liable to cholera. In 1897 the district was famine-stricken. Cholera broke out epidemically in May in two *thanas* which were severely affected by the famine, and did not abate until August, after nearly 4,000 deaths had occurred. In the district of Chittagong the cholera death-rate was nearly four times the average. There were two outbreaks, the first in April, May and June, attributed by the Civil Surgeon to the concentration of the polluted water-supply on account of drought ; the second in November and December, but chiefly in the latter month, when, owing to the rise in the price of the ordinary articles of food, the people were subsisting largely on dried fish. This dried fish, although bad smelling, may, it seems, be consumed in moderate quantities with impunity, but when it was taken into use as a substitute for the every-day diet of rice and *dál*, it gave rise to diarrhœa and predisposed the consumers to be attacked by cholera. Particulars regarding the most unusual cholera mortality in Lohardaga are not given. The district is not included in the list of those seriously affected by famine, but the neighbouring districts of Palamau and Manbhum, where the cholera death-rates were also very high, are included. The lowest cholera death-rates were registered in the district of Darbhanga, ·14 per 1,000 against a quinquennial mean of 3·27, Jalpaiguri ·30, Saran ·35 and in Muzaffarpur ·35, against a mean in that district of 4·38.

Cholera was more fatal in the towns than in the districts, the millesimal death-rates having been 3·76 and 2·71. Only ten towns, including Darjeeling, Dinajpur, Motihari, Lalganj and Roserha, escaped altogether, and in very many of the towns the rates were

very high. The towns in Chota Nagpur suffered especially, and enormous death-rates were registered in Daltonganj, 23·10 per 1,000, Hazaribagh, 25·07, and Lohardaga, 45·56.

In the province as a whole, the greatest mortality occurred in April, March and August, and the least in January, October and February. The incidence of mortality as usual varied in different localities. In Bengal proper, cholera was most severe in April, March and June; in Bihar, in August, June and July; in Orissa, in July, June, November and August; and in Chota Nagpur, in August, July, September and June.

Thirteen cases and 11 deaths from cholera occurred among the European seamen in the Port of Calcutta, as compared with 23 cases and 18 deaths in 1896. Among the native floating population there were 116 deaths, as compared with 156 in 1896.

Assam.—The cholera mortality in Assam in 1897 was enormous; the number of deaths rising from 17,042 in 1896 to 33,240, and the death-rate from 3·39 to 6·62 per 1,000, as compared with a quinquennial average of 3·70. Although the cholera death-rate was nearly double the average in Cachar, it was a little below it in Sylhet, and the population of the latter being about six times as large as that of the former, the average death-rate in the Surma Valley was but little in excess of the quinquennial average—3·79 per 1,000 as compared with 3·58. In the selected areas of the Khasi and Jaintia Hills cholera was a little less prevalent than usual. The enormous increase in the cholera death-rate then, was due to the prevalence of the disease in the Brahmaputra Valley. Even there the death-rates were lower than usual in Nowgong and Lakhimpur, but in all the remaining districts the rates were very high, and in Kamrup (17·48), Goalpara (10·35) and Sibsagar (9·75) they were enormous.

The seasonal distribution of the disease was not that of an ordinary year. In the Surma Valley cholera is generally most fatal in the cold weather months; in 1897 the death-rates were less than the average in the months of November and December, and less than half the average in January, whereas in March, April and May the rates were rather more than twice the average. In the Brahmaputra Valley there are two seasons of cholera prevalence, April, May and June, and November and December; in 1897 the monthly rates were all far above the average and the maxima occurred earlier, in March, April and May, and in October, November and December.

In the towns the cholera death-rate averaged 15·44, against 6·43 in the country, but it must be remembered that the towns are small, and that the rates were raised by the deaths of immigrants at the coolie depots. Thus, the highest urban cholera death-rates were 62·08 in Tezpur, and 58·86 in Dhubri, but in the former 233 out of 249 deaths, and in the latter 216 out of 284, occurred among immigrants. A high rate of 13·56 per 1,000 in Silchar is accounted for in the same way. In Barpeta, where the cholera death-rate was 52·59 per 1,000, 504 out of the 625 deaths occurred in August, and the severity of the outbreak is attributed by Colonel Stephen to pollution of the water-supply produced by disturbances caused by the earthquake.

Although the cholera mortality of the year would have been heavy in any case, there seems to be every reason to believe that the total mortality was greatly enhanced as a result of the suffering and privation to which the people were exposed by the floods which resulted from the earthquake.

The mortality among the immigrant coolies was entirely exceptional, no less than 474 dying on steamers going up the river and 934 in the depôts after landing.

The mortality among the coolies on the tea gardens, calculated on their population in 1891, was 6·83, against 6·66, the average among the general population of the districts in which the gardens are situated; but, as pointed out by the Chief Commissioner, the population of the tea gardens has increased by 30 per cent. since the census, and, calculated on the actual populations, the cholera death-rate on tea gardens was 4·91 per 1,000. Taking the actual number of deaths, in the districts, excluding the tea gardens, the number of deaths rose from 14,885 in 1896 to 30,081 in 1897; on the gardens the number of deaths rose from 2,112 to 3,108. Roughly, the mortality among the general population was doubled, while the deaths of tea garden coolies increased in number by one-half.

North-Western Provinces and Oudh.—In a year of famine, when the general health of the people was reduced and great numbers of the very poorest were gathered together on relief works, it might be expected that the mortality from cholera would have been exceptionally great. But this was not the case. The mortality was less than half the average. Time after time, cholera appeared in epidemic form among the relief-workers, but the measures adopted never failed to check the disease. These measures were, " the

" careful preservation of the purity of the water-supply, the prompt removal of the people " from the infected area, and the breaking up of large bodies of people into smaller " manageable units."

The total number of deaths was 44,208, equal to a death-rate of ·94 per 1,000, as compared with 1·47 in 1896, and an average of 2·16 for the five years preceding that under report. In no district was the cholera death-rate very large; the highest rates being recorded in Pilibhit (3·21), Jalaun (3·03), Hamirpur (2·86) and Banda (2·72); in nine districts the rates were less than ·10 per 1,000, and in no less than seven of these the numbers of deaths were under ten, three of them, Almora, Garhwal and Muzaffarnagar, escaping altogether. The rural cholera death-rate was ·91, against 1·38 in the towns. Twenty-eight of the latter entirely escaped, and in only a few were high cholera death-rates recorded—Sandila (9·40), Ramnagar (9·10), Fatehpur (8·42), Barhaj (7·00), Kalpi (5·58), Azamgarh (5·40), Mubarakpur (5·29) and Gorakhpur (4·45).

There was but little cholera in the provinces in January and February; a rapid rise in March was followed by a gradual rise till June, when there was another sudden rise; rates rose gradually to a maximum in August, and gradually fell until October, when the fall to the end of the year was rapid.

Punjab.—Cholera was present in only five districts, and the total number of deaths recorded as due to it in the Punjab was 622, equal to a death-rate of ·02 per 1,000, as compared with ·25 in 1896, and ·80 the quinquennial mean. Of the total, 538 deaths occurred in Hissar, 61 in Gurgaon, 15 in Rawalpindi, 6 in Gurdaspur and 2 in Lahore. The average district rate was ·02, as compared with ·13 in the towns. The disease appeared in only five towns, Hissar (cholera death-rate 3·98 per 1,000), Hansi (2·63) and Bhiwani (2·37) in the Hissar district, Rewari (2·18) in Gurgaon, and Lahore (·01). All the deaths occurred between June and October, inclusive, the largest number being registered in September.

Central Provinces.—The cholera returns of the Central Provinces in 1897 afford a remarkable contrast with those of the North-Western Provinces and Oudh; in both provinces famine was present, but while in the latter the cholera mortality was that of an ordinary year, in the former it surpassed those of all previous years, except 1869, when the prodigious rate of 10·50 per 1,000 was computed.

The total number of deaths registered was 57,131, equal to a death-rate of 6·01 per 1,000, as compared with 5·58 in 1896, 2·44 the quinquennial mean, and 5·96 in 1889, another year of extraordinary cholera prevalence. In every district, except Burhanpur, the cholera death-rate was higher than the district mean, and in twelve of the twenty districts the rates were higher than they were in 1896. Cholera deaths were returned from 221 of the 233 circles of registration, every circle in 12 of the districts being attacked. As in 1896, the greatest mortality was registered in Mandla, and the least in Burhanpur; but while the rate in Mandla fell from 15·75 per 1,000 to 11·62, the rate in Burhanpur rose from ·68 to 73. The next highest rates were 10·04 and 9·87 recorded in the adjoining districts of Raipur and Bilaspur; while the next lowest were 1·96 in Jubbulpore, which marches with Mandla, and 2·93 in Wardha.

The average millesimal cholera death-rate in rural areas was 6·11, far higher than the average urban rate of 4·87, but many of the smaller towns suffered in an extraordinary degree. The highest rates were 37·12 per 1,000 registered in Drug, in Raipur, 35·49 in Sironcha, in Chanda, and 24·22 in Seoni. Ten towns, among them Burhanpur and Jubbulpore cantonment, escaped altogether, and the rate in Jubbulpore city was only ·29. The comparative immunity enjoyed by Raipur town in 1896, when the death-rate in the town was rather less than a third that of the district, was not continued; in 1897 there were 111 deaths in the town and the death-rate, 4·67, was just under half that of the district. It seems, however, that the general water-supply of the town, to the good quality or which the relatively low death-rate in 1896 was ascribed, was bad in 1897.

The death-rate increased steadily from January (283 deaths) to April (6,334); in May there was a rapid rise (15,642), and the maximum (21,125) was reached in June; in July there was a very rapid fall (5,243), which was maintained until December when the minimum (51) was reached. The greatest mortality in most of the districts was recorded in June, but in Narsinghpur and Burhanpur the largest numbers of deaths occurred in April, in Murwara, Hoshangabad, Balaghat and Nagpur in May, and in Chanda in July. At the beginning and end of the year many districts were free from the disease, and even in the three months when the epidemic was most severe, two districts were unaffected. In Burhanpur there were only two fatal cases in May and none in June or July; and in

Chhindwara no death was reported in April. The average death-rate of males (6·47) was considerably higher than that of females (5·56); but in Saugor, Narsinghpur, Chhindwara, Damoh and Betul the female rates were the higher, the reported deaths of females being actually more numerous than those of males in the first three of these districts.

Berar.—In a year of famine and distress it was to be expected that there would be a great number of deaths from cholera in Berar, a province where the disease is an annual visitant. The number of deaths was large, 10,122, but it was less than in either 1896 or 1895, when 12,264 and 11,919 cholera deaths were recorded, and the aggregate of these three years is almost exactly equal to the appalling total registered in 1878, the last year of famine, when 34,306 deaths were ascribed to cholera.

The death-rate in 1897 was 3·5, against 4·3 in 1896, and 2·2 the quinquennial mean. The highest district rates were 5·6 and 4·4 per 1,000, recorded, respectively, in Akola and Amraoti, and the lowest 2·6 and ·7 in Basim and Wun, where the highest rates of the preceding year were registered.

In rural areas the average cholera death-rate was 3·1 per 1,000, less than half the urban rate of 6·8. In some of the towns the rates were excessive, particularly in Talegaon (24·8), Karanja (20·6) and Kolapur (19·6), in Amraoti, in which district are located also the only four towns that escaped altogether—Ner Pinglai, Nandgaon Pett, Pusla and Buroor. The towns of Pusla and Buroor have escaped cholera altogether during the last three years, but in 1894 the cholera mortality in them was almost the highest in the province.

The seasonal distribution of the disease was normal; slight during the earlier months, rising through the hot weather to a maximum in August, and then rapidly declining to disappear altogether with the onset of the cold weather in November.

Madras.—Cholera was exceedingly prevalent and fatal in Madras in 1897, and no less than 143,445 deaths from it were recorded, equal to a death-rate of 4·4 per 1,000, as compared with 1·5 in 1896, and 1·3 the mean of the quinquennium. The two districts that suffered most were Ganjam in the extreme north-east and Malabar in south-west. In these districts the death-rates were, respectively, 12·5 and 10·4 per 1,000. In both districts scarcity was severe, and the district medical officers state that diarrhœa simulating cholera was extremely prevalent owing to the people eating unsuitable food. In Malabar the sex distribution of the mortality was peculiar. In that district, as in most of the coast districts of Madras, there is an excess of females in the population; but in Malabar alone, not only was the actual number of females who died larger than the number of males who died of cholera, 14,616 as compared with 12,917, but the female cholera death-rate was much the higher, 11·0 against 9·9. The next highest death-rate, after that recorded in Malabar, was 7·5 per 1,000 in Tanjore, and this was followed by 6·0 in Madura and 5·9 in Anantapur. The lowest rates were ·5 and ·3 recorded, respectively, in Nellore and Madras.

In rural areas the average death-rate was 4·3 per 1,000, against 5·0 per 1,000 in the towns. Only two of the latter escaped altogether, namely, Ravadrug and Rajahpalaiyam, but in nine, including St. Thomas' Mount, Ootacamund and Mangalore, the numbers of fatal cases were 5 or less. The highest urban rates were 28·5, 23·6 and 23·1 per 1,000 registered, respectively, in Cannanore, Parlakimedi and Calicut, and in no less than seventeen other towns rates in excess of 10 per 1,000 were recorded.

The disease was exceedingly prevalent in January (19,721 deaths), it decreased rapidly in February, and then gradually declined to a minimum in April (4,165); the number of deaths then gradually rose until August (20,688), when the maximum was reached; the numbers again declined until November (8,459), and then suddenly rose again in December (16,378).

Coorg.—Although the cholera death-rate in Coorg was only ·61, the disease was unusually prevalent there as compared with past years; there were 106 deaths, against an aggregate of 150 in the last ten years. Only nine deaths occurred in the towns, all in Virajendrapet, where the death-rate from cholera was 2·02 per 1,000.

Bombay.—The number of deaths registered as due to cholera in Bombay was 57,109, a number which has not been nearly equalled since the famine year, 1877, when the number of deaths from cholera was 57,228. In its broader features the distribution of cholera in 1897 resembles the distribution in 1877. In both years Sind was free from the disease, and the districts of Gujarat suffered comparatively little; but in 1897 the districts of Kolaba, Khandesh, Ahmednagar, Nasik, Poona, Sholapur and Satara suffered more severely

than they did in 1877, while the remaining districts, although the disease was very prevalent in them, suffered less.

The death-rate in 1897 was 3·03 per 1,000, as compared with 1·88 in the previous year, and a quinquennial average of 1·48. As has been indicated, the province of Sind was practically free from the disease, only one death occurred in the town of Karachi in September. No fatal case was reported in Ahmedabad, only seven were reported in Panch Mahals, and ten each in Broach and Kaira. The highest district death-rates were registered in Satara (9·03), Poona (8·62), and Belgaum (7·41), and high rates, over 4 per 1,000, were recorded in Bijapur, Sholapur, Kolaba, Ahmednagar and Nasik.

The average cholera death-rate in rural areas was 3·14 per 1,000, as compared with 2·26 in the towns. Twenty-two of the latter escaped entirely, and in twelve others, including Surat (1) and Broach (3), the numbers of deaths recorded were less than ten. By far the highest urban death-rate from cholera was 23·63 per 1,000 in Nasik, where 650 deaths occurred. In Pandharpur the death-rate was 12·33, in Kalyan 9·68 and in Junnar 9·58.

Nearly as the local incidence of the epidemic of 1897 resembled that of 1877, there is not much in common in the monthly distribution of the disease in the two years. In the earlier epidemic the disease prevailed steadily throughout the year, reaching its maximum of 8,309 deaths in June, and then gradually declining to a minimum in December. In 1897 the vast majority of the deaths occurred between May and August, the maximum of 14,749 being reached in July. As in 1877, the smallest number of deaths was recorded in December.

Burma.—The number of deaths from cholera registered in Lower Burma was 8,538, and it is necessary to go back to 1888 and 1873, when 15,982 and 8,109 deaths were, respectively, recorded, to find this total exceeded or nearly equalled. The death-rate was 1·89 per 1,000, as compared with ·66 in the previous year, and 1·07 the quinquennial average. The disease was most severe in the deltaic districts of Myaungmya (death-rate 5·10 per 1,000) and Thongwa (4·41), in Thayetmyo (3·72) and in Tharrawaddy (3·28). The southern districts of Tavoy and Mergui escaped entirely, and Sandoway, although it is bordered by Thayetmyo (3·72), Prome (1·76), Henzada (1·72) and Bassein (1·84), in all of which the disease was more fatal than usual, is reported to have been exempt. The other two districts of the Arakan division, Kyaukpyu (·12) and Akyab (·63) were, however, unusually free from cholera.

The urban cholera death-rate was 2·88, as compared with 1·74 per 1,000 in rural areas. In six towns no death from cholera was reported, and in other five the number of deaths was less than six ; but the rates were upwards of ten per 1,000 in five towns, the highest being 35·52 and 12·57 recorded, respectively, in the small towns of Zigon and Myanaung, where the populations are so small that a comparatively small epidemic gives an enormous death-rate.

The disease was present in ten districts out of eighteen in January, and the number of deaths reached the maximum in March ; in April and May there was a slight decline, which became considerable in June ; in July the number of deaths again rapidly increased, and in August almost as rapidly decreased, after which there was a steady fall to the end of the year, the minimum being registered in December.

Summary of cholera registers.—The following paragraphs have been compiled from the official reports of the occurrence of cholera among European and native troops and among prisoners. It is apparent that, owing to the press of more urgent work, the materials for these reports are not always collected at the time ; and the reports, in consequence, too often lack precision, even when they have been drawn up by the same medical officer who was in charge at the time of the outbreak.

Cholera occurred among European troops at 23 different stations. There were in all 132 cases and 85 deaths, a case-mortality of 64·39 per cent. In eleven instances the attacks were single, and seven of these single cases ended fatally. Three of the single cases, of which two were fatal, occurred in regiments on their way to the front. All the outbreaks were small, except at Sitapur, where there was a very severe epidemic among the men of the 1st King's Shropshire Regiment.

Among native troops the disease appeared in 34 different stations, and among 43 bodies of men. Excluding the cases of three European officers, all of whom died, there were 201 attacks and 121 deaths, a case-mortality of 60·19 per cent. Of the total, 100 cases and 58 deaths—case-mortality 58 per cent.—occurred among regimental followers. There were 13 single attacks, and 10 of these ended in death. The vast majority of the outbreaks were slight, and in only four instances were there upwards of 10 cases.

Cholera appeared in 82 jails during the year, and in 16 of them on more than one occasion. There were in all 975 seizures and 412 deaths, equivalent to a case-mortality of 49·43 per cent. Although cholera was so widespread among the prison populations, only the Punjab, Berar and Coorg escaping, the majority of the outbreaks were slight. In 24 jails single cases only occurred, but 17, or 70·83 per cent., of these cases were fatal. In the following jails the outbreaks were very severe: Coimbatore, 280 cases and 113 deaths, Rajahmundry, 202 cases and 75 deaths, Thana, 63 cases and 37 deaths, Moulmein, 63 cases and 37 deaths, and Hazaribagh, 26 cases and 19 deaths.

Diarrhœa seems to have been very seldom specially prevalent at the time that cholera occurred. Among European troops it was unusually prevalent on only two occasions, namely, at Jhansi and Nusseerabad ; and among native troops on no single occasion. At the time of the outbreaks in the jails at Purulia, Hazaribagh, Rajmahal, Jaunpore, Rajahmundry (during each of the three outbreaks) and Bassein, an unusual prevalence of diarrhœa was noted.

The statement below shows, as nearly as possible, the numbers of buildings occupied by the various bodies of men attacked by cholera, and the proportion which furnished cases of the disease :—

Communities.	Number of buildings occupied by bodies of men attacked.	Number of buildings which furnished cases.	Percentages of buildings which furnished cases.
European troops	572	52	9·29
Native troops and followers ...	12,549	153	1·22
Prisoners	879	179	20·36

Cholera occurred during all conditions of weather, but no special relation between particular meteorological conditions and the occurrence of the disease was established.

In most instances in 1897 cholera was prevalent throughout the districts in which the bodies of men attacked were located, so that evidence of importation, in the sense in which the term is used here, namely, the bringing of cholera from a place where it existed to a place where it did not exist, and its subsequent spread in the latter, could not be adduced.

In only six instances, when European troops suffered, the presence of cholera was not reported in the surrounding villages. These instances are the following :—At Fyzabad, a man was seized two days after his return from Calcutta where he had been on escort duty ; the man died, but the disease did not spread. At Muttra, a man who was in hospital and another living in a tent were attacked on the same day : both men had been eating country bacon, and had no other circumstance in common ; both died, but the disease did not spread. Two men of the 1st Dorsetshire Regiment suffering from cholera were removed at Umballa from the troop train carrying the regiment to the front : one man died and the other recovered ; and no other case occurred in the regiment, which was detained at Umballa for eleven days, or among the troops in that station.

The next statement shows the numbers of persons who were in attendance of one kind or another on cases of cholera, with the numbers and percentages attacked :—

Communities.	Number of cases of cholera treated.*	Attendants.		Percentage of attendants attacked.
		Number.	Number of these attacked.	
European troops	128	269	1	0·37
Native troops and followers	182	449	5	1·11
Prisoners	970	847	30	3·54

* Cases not treated in hospital are excluded when the number of attendants is unknown.

A European orderly, one of nineteen persons in attendance on two cases at Fort Allahabad, was seized four days after the second case of cholera was admitted to hospital. The medical officer attributed the man's attack to neglect of the precautions he had been instructed to take.

Of the five persons attacked while in attendance on native soldiers and followers, two belonged to the regiment at Sirdarpore and a third was the sister of a lascar at Raipur ; these attacks were attributed by the medical officers to neglect of precautions. The fourth case, that of a sweeper at Bolarum, was not ascribed to attendance, but to the man's wandering in an intoxicated condition in the *bazaar* where cholera was prevalent. The fifth case was that of a sowar at Hingoli, who was in attendance on his child ; but the medical officer did not think the attack was due to the attendance.

Not included among attendants attacked, is the case of the medical officer of the 1st Madras Lancers. The regiment was in cholera camp, at Sangana Kulli, and the epidemic had apparently ceased on the 18th October. On the 30th the medical officer and two grass cutters were attacked and died. The reporting officer writes, " His attack was not " due to attendance on any of the cases, none having occurred in camp between the 18th " October 1897 and the 30th October 1897."

The large number of attendants who suffered in the epidemics among prisoners is in part due to the unusual prevalence of cholera among the people generally. In two or three cases the attacks might fairly be attributed to attendance, but medical officers sometimes appear to forget that attendance on cases of cholera does not afford immunity from the incidence of the disease, if it is specially prevalent in the locality. For instance, at Coimbatore, 13 attendants were attacked, and the medical officer concludes that their attacks were due to " close attendance on the affected." In the epidemic there were 280 cases among a population 1,054 persons. Omitting the medical staff, all of whom escaped, there were 91 convict orderlies of whom 13 got cholera. That is to say, out of the general body of 963 prisoners, 267 were attacked, or 27·73 per cent., while of 91 orderlies 13, or only 14·29 per cent., were attacked.

Except at Kirkee, where the method in use for the removal of waste water is condemned, no defect in the general sanitation is noted in connection with any outbreak among European troops.

Beyond scantiness of the water-supply in several instances, overcrowding at Shillong, and defective drainage at Sirdarpore, few complaints regarding the sanitary surroundings of the native regiments in which cholera occurred are made.

In the jail reports complaints are more frequent, principally of overcrowding and defective drainage ; in some instances the water-supply seems to have been bad ; while in a few cases the general sanitation of the jail seems to have been at fault.

The effect of moving European troops, when this remedy was required, was invariably beneficial not only in respect of the cessation of cholera, but as regards the general health.

The movement of native troops was always successful, and the effect on the general health was good. Prisoners were moved in very many instances, and with few exceptions with the best results, not only in checking cholera, but in improving the general condition. The general health of prisoners moved into camp was affected more or less injuriously by heat and glare at Minbu ; exposure to rain gave rise to dysentery at Hazaribagh ; and the chilly mornings and hot days set up dysentery among the prisoners camped out at Vellore.

Small-pox.

The deaths from small-pox in 1897 in the parts of India under registration numbered 167,318, or 25,875 more than in the preceding year, the ratio per 1,000 of population being 0·77 against 0·65. The increase in ratio affected six of the twelve provinces in the table ; but was much the greatest in the case of the North-Western Provinces and Oudh.

The mortality rose month by month from the beginning of the year up to its maximum in April, then sank month by month to its minimum in October, and, finally, rose again to the end of the year ; and in all the provinces the maximum was in the first half of the year, the minimum in the second. Of the total deaths of the year, 81 per cent. occurred in the first half, and 19 per cent. in the second. The months of greatest mortality were April, May, and March, and those of least mortality, October, November, and September. Each of the first five months had more deaths, and each of the last seven, fewer, than the corresponding months of 1896.

The following shows the mortality from small-pox in the different provincial registration areas of India in 1897, month by month :—

Statement showing the deaths from Small-pox registered in the different Provinces by Months during the year 1897.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.		RATIO OF DEATHS PER 1,000 OF POPULATION

Bengal.—The number of deaths recorded as due to small-pox in Bengal in 1897 was 19,655, or 0·27 per 1,000, as compared with the 0·19 of the previous year, and with the average of the past ten years, which was 0·16. Most of the districts of the Patna, Orissa, and Burdwan Divisions had ratios above both the quinquennial and the decennial averages. The disease prevailed with epidemic intensity in Shahabad, Puri, and Gaya (ratios over 1 per 1,000). The Civil Surgeon of Shahabad thought that the severe prevalence might be due to the large number of unprotected people who came in search of work from other districts. The Civil Surgeon of Puri says that the infection came from the adjoining Madras district of Ganjam, and that the adult male population, who had either been inoculated in their childhood or had had the disease in a mild form before, were the chief sufferers. According to the Civil Surgeon of Gaya, almost all the deaths in the town of Gaya were among the unprotected and the outsiders, and the prevalence of the disease in the rural areas was due to the great opposition on the part of the people to vaccination. The number of district ratios not less than 1 per 1,000 was 3 ; not less than 0·5 per 1,000, 3 ; not less than 0·05 per 1,000, 20 ; and less than 0·05 per 1,000, 20. Only in the Jalpaiguri district was there no death. The urban death-rate was 0·26, as compared with a rural rate of 0·27. Mortality ratios of over 2 per 1,000 distinguished the towns of Bhadreswar and Serampore in the Hooghly district, and eight other towns had ratios of over 1 per 1,000. The number of deaths among children under 1 year of age rose from 1,924 in 1895 to 2,850 in 1896, and again to 4,351 in 1897 ; and among children 1 to 12 years of age, from 4,707 to 7,026, and again to 9,787 ; while the percentage of children's deaths in the total small-pox mortality of all classes rose from 50·92 in 1895 to 73·43 in 1896, but fell to 71·93 in 1897.

As in the preceding year, one non-fatal case occurred among the European seamen in the port of Calcutta ; while among the native floating population there were 8 deaths against 1 in 1896, the respective ratios being 0·31 and 0·03.

Assam.—In Assam there were 5,420 deaths registered during 1897, against 5,444, yielding a ratio of 1·08 per 1,000, the same as in 1896, against the 0·69 of the preceding quinquennium. The highest district death-rate, 5·10 per 1,000, representing 2,333 deaths, was recorded in Sibsagar ; Lakhimpur and Kamrup following with ratios over 2 per 1,000. One district had a ratio of over 1 per 1,000, one of over 0·5, and three districts ratios of not less than 0·05. Since a slight outbreak in 1881–82 very few small-pox deaths had occurred in the Nowgong district. The Civil Medical Officer reports that a brass-worker of the *Moria* caste was attacked with small-pox at Nachonipara in the Sibsagar district, and was brought in a boat, while suffering from the disease, to Moriagaon near Kuaritol, in the eastern portion of the Nowgong district, in the beginning of April 1897.

The disease afterwards spread in that village, in which about 130 persons were attacked and 13 died. From this village small-pox spread to neighbouring villages, and before the end of the year the greater portion of the Nowgong district was affected. As soon as the outbreak was reported, all arrangements were made to vaccinate unprotected persons in the affected villages, but in almost every case parents refused to allow their children to be vaccinated. The Sanitary Commissioner himself did all that he could personally. But "the people are," he says, "so bigoted that comparatively little vaccination was done "during the season; and as a large portion of the population is unprotected, the "probability is that small-pox mortality in Nowgong will be large in 1898." In ten towns there were no deaths from small-pox, and in the others the mortality ranged from 5·62 per 1,000 at North Lakhimpur to 0·14 at Sylhet, the provincial urban ratio being 0·50. On the other hand, the provincial rural ratio was 1·09, the district extremes being zero and 5·16. Among infants under one year of age there were 1,062 deaths, nearly 20 per cent. of the total; and among children between one and twelve, 2,846 deaths, near 53 per cent. of the total.

North-Western Provinces and Oudh.—The lowest recorded death-rate from small-pox in the twenty-six years 1871–96 was 0·04 from 1,968 deaths in 1895. But in 1897 there were 87,127 deaths from small-pox, giving a ratio of 1·86 per 1,000. The increase over 1896 was 44,356 in actual deaths, and 0·95 in the ratio. "This," says the Sanitary Commissioner, "is a considerable increase, and the explanation is possibly to "be found in the peculiar climatic conditions prevailing. Small-pox appears to be in "this country especially a disease of dry weather, its virulence increasing with "heat . . . It appears to have had little or no connection with famine: certainly "it did not particularly affect the distressed districts." The districts with mortality ratios not lower than 5 per 1,000 were Sultanpur, Jaunpur, and Bijnor; and there were five districts with ratios not under 4 per 1,000, one with a ratio not under 3 per 1,000, five with ratios not below 2 per 1,000, thirteen with ratios not less than 1 per 1,000, three with ratios not under 0·5 per 1,000, fourteen with ratios not under 0·05 per 1,000, and four with ratios under 0·05 per 1,000. There was no district without a small-pox death; and only 17 of the 97 principal towns escaped. The urban mortality was 0·62 as compared with 1·95 in the rural areas. Omitting the towns without mortality, the extreme urban ratios were, on the one hand, 8·31 at Nagina, 7·59 at Bilgram, 5·94 at Kiratpur, and on the other, 0·01 at Agra. Among infants under one year, 27,526 deaths occurred, against 14,410 in the previous year; and among children under 12 years of age but not under one year, 48,036, against 26,443. Again, the percentage of deaths of the former class of children to the total small-pox mortality of all classes of the population was nearly 32, against nearly 34 in 1896, and that of the latter class of children to the same, over 55, against nearly 62.

Punjab.—After the severe epidemic of 1896 small-pox greatly abated in the Punjab in 1897; the total number of deaths registered being 16,077 against 45,084, and the ratio per 1,000 0·78 against 2·19. As usual, says the Sanitary Commissioner, the lowest death-rate from small-pox was registered in Kangra, the best vaccinated district in the province. The Bannu district had a ratio over 3 per 1,000; the Hazara district, a ratio over 2 per 1,000; ten districts had ratios not below 1 per 1,000; eight, ratios not below 0·5 per 1,000; nine, ratios not below 0·05 per 1,000; and two a ratio below 0·05 per 1,000. The rural mortality was 0·81 and the urban 0·57. The extremes of the town mortalities are far apart owing to the excessive mortalities in certain towns due to a neglect of vaccination, which calls for reform. Rajanpur had a ratio over 9 per 1,000; Nowashar one over 8; and five towns ratios over 5; while the lowest mortality, excluding 47 towns wherein there were no small-pox deaths, was at Rawalpindi, one of the larger of the 151 towns. Of the 16,077 persons who died from small-pox, 5,001, or over 31 per cent., were children under one year of age; and 8,549, or over 53 per cent., children between the ages of one and twelve.

Central Provinces.—The number of deaths from small-pox in the Central Provinces fell from 7,747 in 1896 to 3,641 in 1897, and the ratio per 1,000 of population from 0·82 to 0·38. The quinquennial mean was 0·93. The province was not altogether free from small-pox in any month of the year; but the disease prevailed, as usual, with greatest intensity in the hot months, and declined in the monsoon season. Only three districts, namely, those of the Mahanadi Division, had ratios over 0·5 per 1,000; and the ratios of the other 17 districts lay between 0·05 and 0·5. In the division just referred to the district ratios were all above the quinquennial mean. The rural mortality was 0·38,

and the urban 0·43. The distance between the urban extremes was very great, the highest ratios being 18·08 at Drug, 9·04 at Mungeli, 6·73 at Ratanpur, and 4·14 at Bilaspur, the three last in the district of Bilaspur, and the lowest ratio 0·02 at Kamptee, while 38 towns had no small-pox mortality. In the 3,641 persons that died from small-pox were included 888 children under one year of age, or over 24 per cent., and 1,428 children between the ages of one and twelve, or over 39 per cent.

Berar.—The total number of deaths registered from small-pox was 617 against 810 in the previous year; while the death-rate was 0·22 against 0·28 in 1896, and against 0·20, the quinquennial mean. Out of the six districts of the province one had a ratio of 0·50, one a ratio of less than 0·05, while the ratios of the other four lay between 0·05 and 0·50. The rural mortality was 0·20, and the urban 0·50. While in 25 towns, mostly in the Ellichpur and Amraoti districts, there was no small-pox mortality, Balapur had the maximum, 6·20, and Akola the minimum 0·20. In Balapur, says the Sanitary Commissioner, the Superintendent of Vaccination personally did his utmost to assist the vaccinator in checking the spread of small-pox in the town, and in affording protection to the population, but difficulty was experienced with the Muhammadan inhabitants. The high ratios of seven towns the Sanitary Commissioner considers to be highly discreditable to the responsible town officials, who seemed to have failed in their duty of collecting children for the vaccinators. Out of the 617 persons who died from small-pox 191, or nearly 31 per cent., were under one year of age, and 241, or over 39 per cent., between one and twelve.

Madras.—The number of deaths from small-pox in Madras in 1897 was 21,678 against 9,410 in the previous year; and the death-rate was 0·67 per thousand of the population against 0·29 in 1896, and against 0·6, the quinquennial mean. The highest district ratio was that of Ganjam (11·7); five districts had ratios not under 0·5, fourteen ratios not under 0·05; and two ratios under 0·05. With regard to Ganjam the Sanitary Commissioner quotes as follows from the District Medical and Sanitary Officer :—

> "It must also be noticed that the customs of the Uriyas tend greatly to spread an outbreak of small-pox. The infected rags and mats, &c., are collected and thrown into the open, and the soiled clothing, &c., washed in tanks used for drinking purposes, thus disseminating the disease. Several instances have been brought to notice where the bodies of people dying of small-pox have not been buried, but deposited on tank-bunds or dry beds of tanks and other convenient spots. This matter was brought to the Collector's notice, and orders were issued to prevent this procedure. I fear it will not be possible to entirely stop this custom, nor will small-pox be kept in check until vaccination is made compulsory throughout the district."

The rural death-rate was 0·7, the urban 0·2; while the urban extremes were 5·8 at Palkonda and 0·02 at Coconada. Kampti (4·2) was the only other town with a very high ratio. Children under one year of age furnished 4,573 deaths, or over 21 per cent. of all the persons who died from small-pox; and children between the ages of one and twelve, 10,120, or nearly 47 per cent.

Coorg.—In Coorg the total number of deaths from small-pox registered was 59, against 18 in the preceding year; and the ratio of deaths per 1,000 of population was 0·34 against 0·10 in 1896, and against 1·37, the mean of the quinquennium. Deaths were registered in 26 villages out of the 517 in the province. Of the *taluks* Mercara had the highest ratio (0·82), the lowest being 0·03. The rural death-rate was 0·35, the urban 0·26, Virajendrapet being the only town with any small-pox mortality. No children under one year of age died of small-pox, but twelve, that is over 20 per cent. of all the persons that died of it, succumbed between the ages of one and twelve.

Bombay.—In the Bombay administration there were in 1897 deaths to the number of 3,835, against 6,443 in the preceding year, and the ratio was 0·20 against the 0·34 of 1896, and the 0·19 of the quinquennium. The disease reached its maximum intensity in March, a month earlier than usual, then declined, but rose again in the end of the year. Of the registration district ratios those of the Western and Sind districts were the highest. Two collectorate districts had ratios over 1 per 1,000, one a ratio over 0·5, twelve ratios not under 0·05, and nine ratios less than 0·05. The ratio for rural areas was 0·20. The mean urban mortality being 0·26, the extremes were 10·28 at Umarkot and 0·01 at Ahmedabad. The total 3,835 deaths from small-pox include 1,130 of children under one year of age, or over 29 per cent., and 1,779 of children between the ages of one and twelve, or over 46 per cent.

Lower Burma.—There were 1,950 deaths from small-pox during the year, and the death-rate was 0·43, as compared with 0·37 in 1896, and with 0·42, the mean of the previous five years. The disease persisted throughout the year, but was most fatal in April, May and June, and least so in October and November. There seems to be a general concensus of opinion among district medical and health officers that in the majority of cases inoculation is responsible for outbreaks of small-pox in Lower Burma. In one instance a public vaccinator had to be dismissed for patronising inoculation by private inoculators. The influx of unprotected coolies also spreads the disease. Only one of the three districts of the Arakan Division had a death, and the Tavoy district had no small-pox mortality. Two districts, Pegu and Toungoo, had ratios not less than 1 per 1,000 ; four, ratios not less than 0·5 ; seven, ratios not less than 0·05, one a ratio less than 0·05, and four no mortality. The rural death-rate was 0·45, and the urban 0·31, the extreme town mortalities being 0·91 at Henzada and 0·03 at Prome. Out of the 1,950 persons who died from small-pox 375, or over 19 per cent., were under one year of age ; 890, or nearly 46 per cent., between the ages of one and twelve.

Plague.

Plague is an acute infectious fever, in the causation of which the microbic factor is the *bacillus pestis* of Kitasato and Yersin ; the other factors being a susceptible animal and a suitable environment. It is the only known disease of the class which attacks epidemically and simultaneously man and certain of the lower animals.

Forms of Plague.—Although cases with severe intestinal symptoms have occurred, the experience of the present epidemic in India has so far not furnished any anatomical evidence that the bacillus has actually entered the body of a patient by the alimentary canal below the naso-pharynx ; while the demonstration of its entry by the skin and by the lungs is almost complete. If the bacillus in the penetration of the skin has entered directly into a blood-vessel, or if it is of so virulent a type, or attacks so susceptible a man, that it is able quickly to paralyse and overcome the leucocytes of the lymphatic glands, and pass on into the general circulation, the result is the rapid and fatal Primary Plague Scepticæmia. If, on the contrary, the bacillus, from its position in the tissues, and from its deficient virulence or the refractoriness of the patient towards it, fails to be dealt with by the lymphatic system, the disease assumes the bubonic form, the form which gives the patient the best chance, such as it is, of recovery. For recovery to take place, however, it is necessary that the disease should remain confined to the lymphatic system ; for, if the bacillus should succeed in passing the lymphatic filter-barriers and entering the blood-stream, the patient will almost certainly die of Secondary Plague Septicæmia. The situation of the bubo depends probably on the place of entrance of the virus, but is most frequently the groin, and the next most frequently the axilla. It would have been natural to suppose that plague pneumonia is always a secondary manifestation of plague septicæmia ; but the evidence of those who have studied cases clinically and anatomically in the present epidemic is clearly in favour of the occurrence of primary plague pneumonia. The main forms of plague, then, are :—

1. *a.* Primary Lymph Plague. *b.* Secondary Blood Plague.
2. *a.* Primary Blood Plague. *b.* Secondary Lung Plague.
3. *a.* Primary Lung Plague. *b.* Secondary Blood Plague.

Such are the divisions to which the reports of most observers more or less clearly point, and there is a very general consensus of opinion that the presence of the bacillus in the blood is an almost certain sign of a near approaching fatal issue. The first part of the report of the Austrian Plague Commission, however, speaks of bacilli being found in the blood of patients recovering from the disease, recognises only two forms, gland plague and lung plague, and asserts that the sick man does not die because he has bacilli in his blood, nor recover because he has not, but recovers or dies according to the amount of strength he has to fight against the disease. Further explanation will probably be given in the bacteriological part of the report, which has not yet been published. Simond's idea is that plague is always contracted by skin puncture, and that the difference between bubonic and septicæmic cases is simply due to different degrees of virulence of the microbe, a very virulent microbe attaining at once the lungs or the blood, a moderately virulent one being delayed by the group of lymphatic glands nearest the point of entry.

Clinically other divisions have been made, either as showing the position of the primary lesion, as in the Tonsillar Type, or as indicating the prevalent symptoms, as in the Gastro-intestinal Type.

Pathological Anatomy and Bacillary Distribution.—In primary septicæmic cases there is during life widespread tenderness of the lymphatic glands of the body ; and after death there is found a general involvement of nearly all the lymphatic glands, one member or group of which may show greater enlargement than the others, with a colour dark red or pink according to stage. There are hæmorrhages in the internal organs, the skin, the subcutaneous tissue, the muscles, and the mucous membranes ; parenchymatous degeneration of glandular organs ; swelling of the spleen, lymphatic glands, and bone marrow ; serous or sero-purulent inflammation of the convexity or base of the brain ; often miliary plague nodules in the lungs, liver, spleen, and kidneys, or larger solitary nodules. These nodules consist of masses of bacilli, and the bacilli are also found in the lymphatic glands and their surrounding tissue, in the blood, spleen, marrow of the bones, bile, urine, peritoneal fluid, juice of the base of the lungs, and fluid from the brain. In a case with hæmorrhages into the mucous membrane of the intestine the epithelium was found to be intact, and the bacilli were present only in the vessels and the extravasated blood, not in the mucous membrane or its follicles. In one case the *diplococcus lanceolatus* was found in a patch in the lung without the plague bacillus. In searching for the plague bacillus the examination must be made as soon as possible after death, as the bacillus disappears somewhat rapidly in the decomposing body.

The bubo is usually in the groin of either side, less commonly in the axilla, rarely in the neck, and most rarely in the supratrochlear or popliteal region. The limb corresponding to the bubo is swollen and œdematous, and petechiæ are usually seen upon it, but they are always in greatest number over the site of the bubo itself, and there may be a few over the body generally. The bubo consists of a chain of swollen glands matted together with serous and hæmorrhagic infiltration, and showing changes varying from medullary swelling to blood infarction, and from softening to suppuration and necrosis. The superficial bubo is often found to be continued into an internal bubo, or into a series of internal buboes, the most internal appearing to be the most recent. Death in the bubonic form of plague is so commonly due to secondary septicæmia that it is difficult to say what would be the appearance in a case of death from the pure bubonic form. Swellings, engorgements, hæmorrhages, cloudy swellings are described. In some cases Peyer's patches and the solitary follicles looked distinct, prominent, and slightly swollen ; but these were probably septicæmic cases. In the lungs there was engorgement with œdema, and, rather frequently small hæmorrhages into the lung tissue. The specific bacilli are found in enormous numbers in the glands of the bubo and in the surrounding hæmorrhage, in the latter probably only after the bacillus has gained access to the blood.

The Bombay Plague Research Committee says that there was no autopsy which went to show that the plague bacillus had reached the stomach or intestines, *e.g.*, in food, and had thence infected the mesenteric glands; and the German, Russian, and Austrian Plague Commissions give similar evidence.

In the primary pneumonic form the only marked evidences of disease are found in the lungs, whereas the lymphatic glands and other organs are scarcely at all affected. No petechiæ were observed in the skin, and large internal hæmorrhages were absent ; but petechiæ on the surface of the heart, in the pelvis of the kidney, in the bladder, stomach, and intestines, were commonly present, probably as the result of the toxin circulating in the blood. Throughout the lungs, but especially in the lower lobes, are patches of lobular pneumonia, and sometimes a mixture of hepatisation and catarrh produced a lobar form. Occasionally necrosis and hæmorrhagic infarction were observed, and of course tubercle was sometimes simultaneously present. Sometimes there are bronchial buboes, sometimes not. Plague bacilli are found in abundance in the pneumonic patches, and sometimes in alveoli which show little or no signs of inflammatory reaction. In one case the *diplococcus lanceolatus* was found by the German Commission along with the plague bacillus ; and Sticker states that it may be associated with that, or the streptococcus, or the influenza bacillus.

Histology.—Childe of Bombay, the describer of primary plague pneumonia, treats of the histology of this and the other forms in the report of the Bombay Plague Research Committee. Some German papers on the subject concern themselves with the lesions produced in animals by artificial introduction of the virus.

The Plague Bacillus.—The bacillus is usually stated to have been discovered by Kitasato and, almost simultaneously, by Yersin at Hongkong in 1894; but it seems that the descriptions given of the bacillus by Kitasato and by Yersin were somewhat different, and that that of Yersin corresponds the more closely with what has been found by subsequent observers. Kitasato described the microbe as motile and stainable by Gram's method, Yersin as non-motile and not stainable by Gram's method. Most subsequent observers have agreed with Yersin that it is non-motile, but on the other hand, its motility and the presence of flagella have been affirmed. The bacillus varies much in different circumstances as to the relation of its length to its breadth; but the typical form is that of a short spindle, such as may be obtained from a plague patient or from a cultivation on agar at 37° C. Because its breadth is great in proportion to its length and its ends rounded, it approaches more or less to the form of a coccus, and has therefore been described as a cocco-bacillus; and on agar at 37° C. such cocco-bacilli form chains like those of the streptococcus. In fluid media the chains are still longer, and the individual bacilli also tend to be longer. A peculiarity of these chains is that after every few links there is a kink from two adjacent links being set askew to one another, and long chains show sudden sharp angles or knicks. The bacillus is easily stained by all the ordinary basic aniline dyes, but not by Gram's method. The stain appears chiefly in the poles, leaving the centre of the bacillus unstained, or nearly so. Observers have given differing opinions as to its possession of a capsule when in the tissues or fluids of its host. No spores have been discovered.* The plague bacillus is agglutinated by the serum of a plague patient after the method of Widal.

Cultivation of Bacillus.—The bacillus can be cultivated on all the ordinary laboratory media, but prefers the addition of glycerine. A very favourable medium is said to be an alkaline 2 per cent. peptone solution to which 1–2 per cent. of gelatine has been added. The growth of the microbe in broth is said to be characteristic, in that it resembles much that of the streptococcus, flocculi being deposited. Alkaline broth containing fat, according to Thomson, produces flake-like islands underneath the surface, which fall to the bottom like vermicelli choppings, on shaking the containing flask. This growth appears in 24 to 48 hours, and continues to grow and develop fresh festooned flakes for upwards of a month. On agar at 37° C. pin-head-sized colonies appear in from 24 to 48 hours. The colonies on agar are whitish and transparent, and by reflected light their borders are iridescent. Abel states that the bacillus can grow in acid media, and that it can be cultivated anaërobically; but the former statement is opposed to the large experience of Hankin, and the latter does not appear to be corroborated by other observers. Conflicting statements have been made as to the capacity of the bacillus for surviving and growing in milk, but probably these differences are due to differences of reaction, as Hankin has shown that whenever milk begins to assume an acid reaction, it begins to obtain the power of destroying the *bacillus pestis*. Klein has pointed out a curious diagnostic dimorphism of the colonies grown on the surface of gelatine. Yersin also originally described dimorphism in agar colonies, and maintained that the two different kinds of colony in the same culture possessed different degrees of virulence, and that the milder varieties tended to overgrow and choke the more virulent. Abel corroborates the fact of the dimorphism, but did not succeed in finding the different degrees of virulence. Kasanski also observed dimorphism. Under unfavourable circumstances, such as old dried media, the bacillus forms bloated involution-forms which are useful for diagnostic purposes. Hankin and Leumann discovered that a rapid way of obtaining such forms was to transfer an agar culture to salt-agar. Such forms also occur in the human body, but Hankin found that this was altogether a *post-mortem* phenomenon.

Degree of hardiness of the Bacillus.—The optimum temperature for the bacillus is 37° C., but its growth is also good at temperatures so low as between 22° and 24° C. Below this its growth is retarded; but it has withstood exposure to cold of —20° C., and has survived repeated freezings and thawings. Temperatures above the optimum retard the growth of the bacillus more than those below it; and moist heat at 80° C. kills the microbe in 10 minutes, at 100° C., in one minute. The usual statement that the *bacillus pestis* cannot survive drying requires some qualification. The fatality of drying to the bacillus is directly proportional to the rapidity with which it is conducted and to the temperature at which it is conducted. Thus, rapid drying at 37° C. (the very temperature at which the bacillus flourishes best) is more quickly fatal than slow drying at a lower temperature, and rapid drying at 37° C. is more rapidly fatal than slow drying at the same temperature.

---

* But *see* Schultz in C. B. XXIII., page 597.

Diffused sunlight appears to have no effect, and the number of hours required by the direct rays of the sun to destroy the bacillus depends on the thickness of the layer in which the bacillus lies and the facility with which the rays can get at it. Even when placed in the most favourable circumstances, *i.e.*, when kept moist and sheltered from light and heat, the life of the bacillus placed in *thin* layers on various articles of clothing of common use is generally measured only by days. Experiments have, however, been published, by Gladin among others, which seem to show that on certain materials and under favourable conditions as regards nutriment, moisture, temperature, and shelter, the bacillus may survive for weeks or even months. Some of the most recent experiments, such as those of the German Plague Commission and of Mr. Hankin, are those which give the shortest survival-periods. It is true that Gabritschewsky says that when kept moist and sheltered, in water, agar, pus, or blood, the bacillus can live for months and years; but in the absence of full details of his paper it is not known whether this is merely an inference or is the result of actual observation. Recent experience in Bombay is that the bacillus is delicate and short-lived under all experimental conditions. There is some contradiction between this and the persistence with which the infection has been known to cling to some places; but the explanation may be that for persistence the bacillus requires the help and services of a living host, the possible hosts occupying various heights in the scale of the animal kingdom. Details of the various experiments will be found in the works to which reference is given. It may be said, however, that so long as the microbe remains in life, it retains its virulence, though its action may be delayed; and that its survival depends on supply of nutriment in suitable surroundings.

To ascertain what danger there is from the buried bodies of those dead of plague, Yokote made some experiments by burying the bodies of plague-mice in little coffins. He found that the bacilli died out in from 22 to 30 days, the rapidity of their disappearance being proportional to the amount of heat and putrefaction present, and that the bacilli did not come out into the earth round about the coffin.

Gladin examined a large number of microbes in conditions of rivalry with the *bacillus pestis*, and found that, except in the case of one (*sarcina aurantiaca*), the latter invariably got the worst of it. Among them was the staphylococcus.

Large numbers of experiments on the action of disinfectants on the bacillus have been made by various observers, and particulars of these may be found in the works to which reference is given. Suffice it here to say that the experience of the laboratory was not always found directly applicable to the bacillus in its natural habitats, and that different antiseptics were found best for different circumstances. Those which have been found of most universal application are fire, boiling water, and an acidulated solution of corrosive sublimate. The last is made by adding two parts of a 1 : 250 dilution of sulphuric acid to 1,000 parts of a 1 : 1,000 solution of corrosive sublimate.

The virulence of the bacillus has been observed to vary, and this is one of the factors supposed to determine whether a man shall suffer from the bubonic or the septicæmic form of plague. Yersin and Metschnikoff state that passage through a guinea-pig increases the virulence of the bacillus, and Devell found the same for frogs. Hankin, however, states that, though the same rule applies to mice, passage through rats is, contrary to expectation, attended by diminution of virulence.

The plague bacillus in nature.—It cannot be said that the bacillus has ever been found in nature uncontaminated by man, or that it is often found in the earth, air, or water of plague surroundings. It has as yet never been found in air, but perhaps no experiments have been made with the air surrounding a patient sick of primary plague pneumonia. The plague-like bacilli found in earth by Yersin were not pathogenic, so that their identity is doubtful. Haydon and Gibson have tried in vain for months to find the bacillus in soil and in the floor scrapings of infected houses, and Hankin appears to have met with as little success. Leumann was successful in 3 out of 25 cases, but thinks the floors had been recently contaminated, probably by sputum. Ogata did not succeed in inoculating animals by means of earth from infected localities; but Kitasato obtained a positive result in one mouse with house-dust, the other mice inoculated dying from tetanus. Haydon and Gibson also failed in earth-inoculations, the animals dying of malignant œdema. Wilm reported that he had found the bacillus in one out of three wells near Kowloon (China, opposite Hongkong) at a time when plague was prevalent; and the following is the only instance in which it was detected by Hankin:—

"Sewree Koliwada is a village in the north-east of the island of Bombay, containing a population
" of some 600 Kolis, inhabiting about 150 houses.

" The first case of plague reported in the village occurred on the 12th of December, but it was not " until January that the disease became epidemic. The disease here, as in Worli, was marked with " great virulence, nearly every case being fatal.

" Disinfecting operations were carried on all through December and January in individual affected " houses, but had little or no effect on the spread of the disease. On the 27th January these opera- " tions were extended, and some 200 coolies were placed on the work; they disinfected and " limewashed all and every house; rags and *kutchra* were burned; all roofs were opened for " ventilation; and the place generally had a thorough cleansing. This work lasted five days, and the " spread of the disease was checked. But at the back of the village there was in December and " January a long and narrow pool of water. This pool was daily largely used by the male population " of the village for ablutionary purposes in connection with defæcation. Mr. Hankin in his researches " at this village about the 24th January discovered the plague bacilli in large numbers in this water. " Upon this being known, the pool was thoroughly disinfected with carbolic acid on or about the " 27th January, and the whole field, which was littered with human excrement, was cleaned up. " It is possible that in this incident lies the crux of the situation. Disinfecting operations apparently " up to January 27th had very little effect on the spread of the disease, and it may be conjectured " that its spread was fostered and maintained by the daily use of the water in the pool, especially " when we know that most of those affected were males. The incident, however, is of interest, as " from the 27th January little or no disease occurred in this village, which, although considerably " reduced in numbers, was not altogether depopulated, there being never less than 350 people in the " place. The disease did not form itself into groups, as is usually the case, but was almost evenly " distributed over the village, there being rarely more than one case in a house. This points to an " unusual element in the spread of the disease, and this element General Gatacre believes to have " been the use of the water of the polluted tanks."

If the means of investigation at present available are adequate, these results, so far as they go, indicate that soil, air, and water do not become generally infected during an epidemic, but are only subject to temporary local contaminations.

Dissemination of bacilli from the sick.—In order to understand how far a plague patient is likely to contaminate his surroundings, it is necessary to remember what has been said under the head of " Forms of Plague." A man suffering from pure bubonic plague has no means of disseminating the bacillus, except, it may be, from a skin wound; but, unfortunately, the majority of cases progress towards a fatal termination by becoming septicæmic, the bacillus breaking through the lymphatic barriers into the blood stream. In that case the hæmorrhages, which have been shown to be so common in plague, will contain bacilli, and in this way the latter may come to be excreted by the alimentary canal, by the urinary organs, or by the air passages. It has even been reported that the bacillus has been found in the milk of lying-in women suffering from septicæmic plague. It is much more often found in the urine than the fæces. It has been said by Germano that, as the *bacillus pestis* cannot survive drying more than a day, it is not likely to be conveyed by the air in a virulent condition; but the researches of Flügge on *bacillus prodigiosus* have shown that a microbe can be readily disseminated in a room in the fine spray which results from coughing. In this way plague pneumonia cases may well be supposed to spread infection, and with this supposition the opinions of clincial observers agree. It is precisely in this form of plague that the chief danger to nurses and medical attendants appears to arise.* The fact noticed above that in pure bubonic plague there is no shedding of the virus by the sick probably explains those cases where a woman sick of plague has borne or suckled an infant without communicating the disease to it, and where a suckling with plague has not communicated it to the mother. Thomson quotes Dieudonné of the German Commission as stating that in Bombay in only one case of plague that recovered was the bacillus demonstrated in the blood, and that was in a child 4 years old, with right parotid bubo, in whose blood bacilli were found four times in five examinations. The statements of Kitasato and of Wilm as to the finding of bacilli in the bodies, blood, and excretions of patients days or even weeks after the cessation of active symptoms must be received with reserve. When a bubo has spontaneously softened and burst, its contents are often, if not always, found to be sterile, not to contain any plague bacilli; and in cases where the staphylococcus has gained access to the bubo, it soon overgrows and destroys the plague bacillus. It has always been held that plague can be spread by means of clothes; and from what has already been said it may be gathered that patients' clothes have opportunities of becoming infected, and that under favouring circumstances the bacillus may thereon maintain vitality and virulence for considerable periods. Wilm claims to have cultivated the bacillus from soiled clothing and bedding. Two cases are quoted by Hankin in which it appears that the virus was preserved in clothing for respectively about 36 and about 10 days. The second of these cases will be quoted again

* One attendant who had been in the habit of finishing off the remains of patients' stimulants was ultimately attacked with rapidly fatal plague.

below as showing that the infection carried by clothing is not always directly conveyed to man, but sometimes indirectly.

Mild Cases.—It has already been mentioned that the virulence of the plague bacillus is subject to variation ; and man is less susceptible than the rat. There are also grounds for supposing that among susceptible kinds of animals there exist individual differences of susceptibility. According as a more or less virulent bacillus attacks a more or less susceptible man, there results plague of all grades of severity, from the acute and rapid primary septicæmic cases to such mild cases as have been described by General Gatacre, and by the German Plague Commission. These mild cases were seen as men or boys with one day's fever and slight tenderness of one gland ; or even without fever, but with stuffiness and headache, or pains in the limbs, or slight digestive disturbances, and recovering in a few days ; and the diagnosis was confirmed by the fact of the patients belonging to families suffering from plague, by the undue weakness remaining, and especially by the irritability of the heart left behind. Lyons, on the contrary, reports that no such cases were seen by the Plague Research Committee. Some cases supposed to be plague were found by the German Plague Commission on bacteriological examination to be caused by other microbes, such as the influenza bacillus.

Other factors in causation.—It has been stated that not only are drought and famine* frequent precursors of plague, but that all great epidemics of plague have been preceded by epidemics of influenza. Whether that general assertion be true or not, it is a fact that, besides the drought and famine of 1896–97, influenza has been prevalent in India since 1890. With regard to climate and temperature all that can be said with certainty is that in the hottest and driest part of the year there has been a lull in the plague epidemic ; but how far this is due to the fact that men are more out of doors, and sleep more out of doors in that season of the year than in the cold weather and rains, and how far the recrudescence in the colder seasons is due to the bringing out again of infected clothes, is not known. That plague can exist in the Himalayas of Garhwal and also at the sea-level in the Bombay Presidency is evidence that elevation above the sea-level is of itself of no account in the etiology of epidemic plague. But it seems to have something to say to plague endemicity ; this being probably due to the fact that on account of the cold causing disinclination from ablution the inhabitants of elevated regions are more dirty in their persons, and, in order to economise warmth, more crowded, shut up, and insanitary in their dwellings. Density of population, poverty, dirt, overcrowding, deficient ventilation, may invite plague into a town ; but once the plague has started, it does not confine itself to the worst parts of the town. It has been said that "plague does not go upstairs," and the Health Officer of Bombay shows that fewer deaths from plague occurred in upper stories than in lower ; but statistical objection has been brought by Hankin against this method of stating the case. Certain statements have already been made with regard to the relation between plague and geological formation ; but the subject will be better discussed when more is known about it, when the epidemic has revealed its final boundaries. Men have been attacked more than women, and young adults more than other men. In Bombay there has appeared to be some ground for believing that meat-eaters were less liable than vegetarians, perhaps because, as the Austrian Commission thinks, the latter are usually inferior in stamina. The comparative exemption of Europeans and rich natives has probably been due in great part to their better built houses and to their more fastidious personal habits. It was sometimes noticed that banias were the first to be attacked, or people living above or close to grain-stores ; and this has been connected with the facts that grain attacts rats, and that rats are very susceptible to plague infection. The sight of plague-intoxicated rats in the street in open daylight was often the harbinger of an outbreak among men. The condition of a house in regard to the accessibility of its living rooms for rats is believed by the Health Officer of Bombay, by Mr. Hankin, and by others, to be the most important of all the environment-factors. The dwellings of the poor are badly built, in bad repair, contain articles of food tempting to rats, and are accordingly swarming with rats ; while the houses of the rich are well-built, are kept in good repair, so do not offer thoroughfare for rats, and articles of food are not kept in the sleeping or sitting rooms, but often altogether separately in out-houses.

Animals and natural infection.—The animals which in India have been found liable to natural or spontaneous infection by plague are rats (very frequently), mice, squirrels,

* Refractory animals, such as pigeons when starved, were found by de Giaxa and Gosio to become susceptible.

grey and brown monkeys. Some cases in which cats were suspected of being so infected are mentioned by the Health Officer of Bombay, by Mr. Hankin, and by the medical officers of three affected native regiments ; but bacteriological evidence has not been adduced. In the report of the Bombay Plague Research Committee it is stated that there was post-mortem evidence of one dog having been affected, but there is no mention of bacteriological confirmation. Dogs are also mentioned by two medical officers of native regiments, and squirrels by one. In India the animals noticed to be immune from natural infection are pigs, sheep, goats, horses, cows, birds.*

Rats.—That rats die numerously in times of plague has long been known ; but, since the discovery of the plague bacillus, bacteriological investigation has shown that at such times it is from plague actually that they die. This has been repeatedly verified in India, the bacillus being found in the bodies of rats found dead in streets or houses. By placing healthy and infected animals in contiguity, Yersin proved for mice, and Simond for rats, that the disease is communicable from animal to animal. In the present Indian epidemic, though local outbreaks have occurred in which there was no observed mortality from rats, as in Hardwar, Bellary (1898), and some of the Kathiawar and Punjab villages and towns, yet in most of the reports the mortality of rats and their connection with the spread of the disease are emphatically noticed. Grain depôts were often the first centres in the spread of the plague. The infection having been imported into the colonies of rats that haunt the depôts, spread among them, and they died in large numbers. The grain dealers in this way were sometimes the first human beings to be affected. Rats when sick of plague come out of their holes into the light of day, tumbling about in a dazed condition, so that they have been described as appearing to be drunk or mad, and it appears that their object is to seek water to appease their thirst. When a certain number of rats have died, the remainder are apt to forsake the place ; and it is evident that this migration must aid powerfully in the dissemination of the disease. It is quite possible also that the liberal use of disinfectants, by making the place intolerable to its rats, may have been instrumental in driving rats with infected individuals among them further afield. To avoid this as much as possible, Hankin has recommended the use of corrosive sublimate for infected places, and of odoriferous disinfectants for localities as yet uninfected. It has been said that concealed cases may continue among rats after the human outbreak has ceased, and Simond claims to have actually found such cases. On the other hand, the disease may continue among men after the rats have left the place or have ceased to be found suffering from plague. It is important to note also that after a village has been evacuated by its human inhabitants, the disease may still go on spreading among the rats, with the result that the village may become more widely infected, and therefore more dangerous to occupiers than before. It is supposed that the interval between two outbreaks in an epidemic at a place is the time necessary for the renewal of the rat-population. Mice do not seem to suffer to anything like the same extent as rats. That rats are an important factor in the spread of the disease in a large city is shown by Mr. Snow, the Municipal Commissioner of Bombay :—

" It would be futile to report on or discuss an epidemic of bubonic plague without considering " the part played in its spread, and the propagation of infection by the hundreds of thousands of " rats which infest a city like Bombay. Their presence probably nullifies to an enormous extent " the advantages to be derived from ordinary human remedies, while their absence, if such a " state of things were ever found in cities and towns, would undoubtedly render plague operations " far more effective.

" From the time the bubonic plague had established itself in Mandvi at the end of September 1896, " large numbers of rats were seen running about the streets and coming out of house connection " pipes and drains in a sickly or dying condition. Many of them had buboes actually developed " on the neck and groin. Bacteriological examination was carried out by the various specialists " present in Bombay on numerous specimens, and the plague bacillus was freely detected. It was " thus clearly proved in Bombay from the outset, as has invariably been the case in other places, that " the disease attacks human beings and rodents. Those acquainted with the life-history and " characteristics of the rat tribe are aware, if I may use the expression, of their extremely clannish " habits. They appear to have regular means of communicating to each other any causes or " symptoms of alarm, disease, and danger. As an instance of this I may mention that when the " well-known preparation 'rough on rats' has been used with success in an infested house for " a few days, the rats altogether disappear and will not be found to return for several months, " sometimes longer.

" In almost every quarter of the city where the bubonic plague appeared in force it was preceded " by the presence of dying rats in considerable numbers. This condition was noticed both in the

* de Giaxa and Gosio found starved pigeons become susceptible.

" houses, open streets, and gardens. In addition to this, a regular migration of rats speedily manifested
" itself; its course was, generally speaking, from east to west and thence up the sides and centre of
" the island due north. Minor migrations also took place in the south of the city, and that on
" Malabar Hill was especially noticeable.

" The bubonic plague travelled principally from east to west and then north, throwing out branches
" to the south, and obtaining a footing on Malabar Hill later on. By the commencement of December
" nearly all the rats had disappeared from Mandvi and adjacent quarters of the city, while they were
" noticed in Kamathipura, Tardeo, and Byculla in great numbers, many of them being found dead.
" The bubonic plague followed in their track with unerring regularity. I was so struck with this
" portion of the plague phenomena that, in the end of December and January, I made a series of
" verbal inquiries from natives in various parts of the town. The replies were invariably the same,
" that the rats had disappeared from the centre of the city, and were observed in great numbers on
" the west and north. In my opinion it is useless to seek further for the origin of the severe
" outbreaks in Worli village, Mahim, and Bandra on the west, and Parel, Naigaon, Sion, and Dharavi
" on the northern side. The enquiries I made showed that vast numbers of rats flying from the
" danger of the pestilence moved steadily in those directions and were noticed in numbers in places
" where they had not before caused remarks. In this way not only would the local stock of rats have
" become infected, but the pestilence would be carried far and wide through the various houses.
" The great majority of the rats seem finally to have left the island, for in most of the infected
" localities only a few have been noticed up to the end of July where swarms existed before. The
" probability is that thousands of them crossed into Salsette and were in great measure the cause of
" the outbreak in so many Salsette villages of the Thana District.

" The migration of the rats on Malabar Hill was of later occurrence, as the plague did not get a
" firm hold there till the commencement of 1897. Many rodents were observed dead or dying in the
" houses along the Walkeshwar, Pedder, and Nepean Sea Roads, and subsequently on the ridge of the
" hill, just before disease broke out in force. By the middle of March not a rat was to be seen or
" heard on Malabar Hill, and yet in ordinary times they infest the whole locality and are constantly
" appearing or making their presence known. They have never returned, or only such a few as to be
" unnoticeable. Since last March, on the ridge where they were very plentiful, I have never seen a
" rat, and only a few of the musk tribe remain.

" Precisely the same phenomena as regards rats have been noticed in Karachi during the recent
" epidemic. Dead rats were found in the vicinity of many infected houses as far back as December,
" and in one of the principal streets running through the main bazar dead rats were picked up in
" hundreds during the first week of February, at which period and subsequently plague was raging
" in the vicinity. The march of the rats in Karachi was from west to east, and the outbreak and
" course of the plague in the various districts corresponded with and followed their migration.

" The rats at Karachi finally proceeded in great numbers to the Civil Lines, where they were
" noticed in swarms such as had never before been seen there. The epidemic in these lines was of the
" slightest and practically confined to a few servants of European residents. The obvious conclusion
" is that the rats migrate on the first symptoms of danger, and dropping all their sick and diseased as
" they go along, keep ahead until they reach a place of comparative safety or have obtained freedom
" from the disease. The return of the rats has been noticed in several godowns in Karachi since
" June, and this, coupled with the fact that the plague has entirely disappeared, may be regarded as a
" sign that all danger is over, at all events for the present. It will thus be observed that, as far as it
" is possible to compare a small city like Karachi with Bombay, precisely the same phenomena have
" been observed in regard to the movements of rats and their connection with the propagation of
" bubonic plague.

" The conditions detailed above are of the gravest import, and must largely influence the spread of
" the plague and the efficacy of any measures to be devised against it. It is indeed difficult to see
" how any measures of disinfection or segregation could fully avail until the migration of rats had
" ceased and the infected localities were free of this moving pest. While it is clear that until some
" effective means of destroying the rats *en masse* or preventing their migration is discovered the
" restriction of the spread of plague at its outset in any large city or town becomes an impossibility.
" It is extremely unlikely that any effective measures will ever be devised for dealing with this
" contingency, and while the migration which in Bombay lasted in the various districts for several
" months was going on, any advantages to be obtained from segregation and other measures were
" reduced to a minimum."

In one infected house in Mokundpur in the Punjab as many as 200 dead rats were found; and the finding of them in or near infected houses was in the affected parts of India also very common. They were not always found in the houses in which cases of plague had occurred, but sometimes in the houses surrounding it. Cases of plague on board the steamers *Shannon* and *Patna* were, according to Simond, preceded by the finding of dead rats on board. It has been supposed that careless or incomplete burial is apt to lead to the spread of plague, by giving rats an opportunity of gnawing the dead body, and the following case, which occurred in the village of Khankhanan in the Punjab, shows that the danger may not be altogether imaginary. An old woman died of plague, and her body was locked up in the room for medical inspection. When the medical officer arrived next morning, it was found that the nose and part of one cheek had been gnawed away. The body was burned as soon as possible. In the next few days every house in the block of buildings in which the corpse was found was affected, and, when the houses were afterwards disinfected, a number of dead rats were found in them. If men suffered without rats in Hardwar, rats appear to have suffered without men at Mahim and perhaps Kankhal (at first); the rats of Old Kurla are supposed to have conveyed the

disease to the rats of New Kurla; in some cases the advent of a plague-sick man to a house was followed by plague among men; in some first by plague among rats and then by plague among men; cases have already been given where rats are supposed to have conveyed the plague to men; Hankin quotes the following case from Collie, showing the progression—clothes, rats, men. A man lost his wife at Bombay. Ten days after he took her clothes and jewellery to a house of his in a village near Hurnai in the Ratnagiri District. About a week after dead rats were found in the house and its vicinity. Six members of the family died, the last being the man who had come from Bombay. None of the others had left the village, which after this importation, was severely visited. Cases have already been given in which the order was man, clothes, man, without the intervention of rats. But the most curious cases are those in which the arrival from an infected locality of healthy men, who do not themselves subsequently develop plague, is followed by plague either among the inmates of the visited house, or first by plague among the rats and then among the inmates.

The Bombay Plague Research Committee says it is evident that infection may be carried by rats to persons who have never been brought into contact with plague patients nor with persons visiting plague patients, and whose food and clothing could not have been contaminated in any other way; and Simond (page 636) gives cases which seems to support this view. It seems likely, however, that rats play a greater part in the dissemination of plague within a village or town than in its conveyance from village to village or town to town, this latter being more frequently the work of men, either in person or by means of clothing. It has been stated by Clarkson that if the plague is brought by rats, men are attacked in a few days, but that if it is brought by men, neither men nor rats are attacked for a month or six weeks after; but some of the cases given by Logan and Anderson contradict this. Ogata stated that in Formosa handling dead plague-rats was regarded as dangerous, and he himself seems to have been alive to the possibility that the fleas on the animal might constitute the danger. Simond and Hankin quote a Bombay case in which 20 coolies were employed to gather and dispose of dead rats in a warehouse, and 12 fell ill of plague within 3 days. Simond mentions the case of a coachman who picked up a dead rat and threw it away on the 13th of the month, and was attacked on the 16th of the same month. Hankin gives another case in a man whose duty it was to clean a house in which the bandicoot rats had been attacked, and to remove the dead rats. An important point noticed by Simond is that when a man gets plague as a result of handling a dead rat, his bubo is at least just as often inguinal as axillary. This seems to lead up to the idea that though the rat is an important agent in the spread of plague, it is not absolutely necessary, and that there is a missing link between the rat and man. Simond says that so long as the rat's body harbours fleas it is dangerous, but that after the fleas have deserted it (probably in about 24 hours) it can be handled with impunity. Notwithstanding the opposite opinion of Bitter and Rogers, it would appear that in India rats have played a very important part in the dissemination of the disease; but Payne and Hankin both notice that rats may not have had much or anything to do with the spread of plague in England in the old days; and Hankin suggests that even in India the importance of its rôle may be different in towns and rural areas, or even in one part of India and another.

Animals and Artificial Infection.—Haffkine found that horses, goats, cows, and sheep were immune against artificial infection by inoculation. The German Plague Commission found pigeons,* fowls, geese, pigs, to be absolutely refractory, and dogs almost so. In the case of cats, sheep, goats, cows, horses, there was more or less general and local reaction, but no plague developed, and all the animals recovered. Of all the animals tested, says the German Plague Commission, the rat is by far the most susceptible. Simple inoculation with the smallest quantities of a culture invariably produces fatal plague in a few days. But so susceptible is the rat that it is not necessary to wound it at all: it can be infected from the unwounded, mucous membranes, and by way of the alimentary canal. Rats died whose conjunctiva or nasal mucous membrane had been merely touched with a small quantity of a pure cultivation. Others died after having been fed with very small quantities of bacillary culture, or after having gnawed the bodies of rats dead of plague. As this gnawing of the bodies of their own dead is a common habit of rats in a state of freedom, it is easy to see one reason why plague spreads so rapidly among them. Some rats into whose mouths pure cultivation was trickled died of plague. In one of the five cases the path of infection could not be traced; but in the others it was

* Found by de Giaxa and Gosio to become susceptible after starvation.

either aspiration into the lungs, or, as shown by the presence of local buboes, through the mucous membrane of the mouth. The grey monkey, says the German Plague Commission, is as susceptible as the rat to inoculation, natural or artificial, by minimal quantities of the virus through the skin ; while the brown monkey, being refractory to small quantities, can only be inoculated artificially. It has since been shown, however, that the brown monkey is susceptible to natural infection, though, possibly, not so readily as the grey. To give plague through the alimentary canal to brown monkeys, they must be fed with large quantities of plague culture. The animals die in a few days, and show severe hæmorrhagic infiltration of the stomach and intestines. Hankin considers that in order to infect a rat by feeding, the bacillus used must be a very virulent one ; and Yersin, Calmette and Borrel state that plague bacilli directly taken from man are effectual. Yersin found that he could infect mice sometimes, rats almost always, by feeding them with pure culture, or with pieces of plague-spleen or liver. Sticker says that intestinal plague can be demonstrated by feeding rats and monkeys, there being lesions of the mucous membranes and symptoms like those of intestinal anthrax or malignant enteric fever. Bandi and Balistreri found that in guinea-pigs plague by feeding was a more chronic process than plague of other introduction, and that it sometimes resulted in secondary plague pneumonia. Klein discovered that in guinea-pigs dead of plague produced by sub-cutaneous injection of a virulent culture, plague bacilli could be found on the free surface of the mucous membrane of the trachea and larynx, and in the slimy fluid contained in the inflamed duodenum. Wyssokowitz and Zabolotny in Bombay found that, while they could give primary plague-pneumonia to monkeys by injection of plague bacilli into the trachea, injection into the stomach did not produce plague, though any little wound of the buccal mucous membrane readily led to infection. Simond obtained negative results from feeding rats, mice, and monkeys ; also from inhalation in a monkey ; also from application to a little wound in a grey monkey. In a note to Simond's paper Roux says that it is quite easy to infect rats by placing on their nasal mucous membrane, without excoriating it, a few plague bacilli from an agar culture or from the spleen of a plague-animal ; and suggests that it would be interesting to know whether the nasal mucus of rats affected with plague is infectious. Wyssokowitz and Zabolotny, experimenting with monkeys, found that if the amount of virus inoculated by the skin was great there was œdema ; but a small wound made in the palm of the hand with a needle showed absolutely no reaction, and quickly became invisible, though a local bubo formed, and the animal died in from 3 to 7 days. No reaction at the wound was discoverable at the *post-mortem* examination. Similarly, a monkey inoculated by a pin-prick on the foot developed inguinal and retro-peritoneal buboes, and died in 10 days. Lyons corroborates this account. Mice and rabbits are also among the animals to which plague can be artificially communicated.

Insects.—Yersin in Hongkong, having noticed a number of dead flies in his plague laboratory, triturated them with water, and injected them into a guinea-pig, with the result that the animal died of plague. Nuttall afterwards found that flies fed with plague organs, though they ultimately died, could continue to go about several days with still virulent bacilli in them. In Formosa, Ogata counted 15 and 20 fleas, respectively, on two dead rats found on the road, but on a rat which had been dead for some hours he found none. He rubbed up seven of the fleas found on the dead rats with water, and injected them into mice. One mouse died, the other did not. Some guinea-pigs in his labratory about this time died of plague, and he suspected that the infection might have been conveyed by insects, if not by food. In the fleas taken from the dead rats he discovered virulent bacilli, and recognised that the bacilli might in this way be conveyed to man ; and he recommends that the sick of plague should, for the sake of others, be kept under mosquito-curtains. Hankin noticed that ants cut up dead rats, and carried the fragments off and about, and therein he recognised a danger ; but, as they did not die themselves, and did not retain the infection long, he considers the danger not great. They were found infected only where rats were dying, not where men only were dying. The German Plague Commission considers it doubtful whether insects can inoculate the disease, and certain that mosquitoes cannot, looking to the immunity of sick attendants, who are constantly being bitten. They found, however, that fleas taken from a rat found dead contained virulent bacilli, which, inoculated into a guinea-pig, produced plague. Sticker, one of their members, formed a decided opinion as to the rôle of insects above-ground, as contrasted with the rôle of rats underground, mentioning especially those which feed on living or dead rats—ants, pediculi, and perhaps mallophagi and acari. Except in the case of pneumonic plague, he considers insects the chief agents of infection-carriage from the sick. Simond found that the flea which infests rats attacks both men and dogs. A

healthy rat keeps itself free from fleas ; but when a rat falls sick, and loses the energy to keep itself clean, the fleas multiply upon it and overrun it. In several cases he found in the intestinal contents of such fleas bacilli morphologically identical with those of plague. The fact that he had no opportunity to cultivate them matters little in view of the success obtained by others, as noted above. He inoculated three mice with triturated fleas, and one of the mice died in 80 hours of plague. The others died in 9—12 days, but the bacillus could not be found in them. A rat suspected of plague was placed by Simond in a large wide-mouthed glass bottle. It was seen to have a few fleas upon it, and 20 more from a cat were thrown in upon it. At the end of 24 hours the animal seemed to be dying. There was then lowered into the bottle a little iron cage with only one side grated, containing a small rat. The first rat died soon after, but its body was left in the cage for 36 hours. It was found to have died of plague. The young rat remained in the cage and bottle. It died on the fifth day of characteristic plague. Three more similar experiments were afterwards made, one successful in the case of a mouse, and two unsuccessful in the case of two adult rats. Simond attributes the two successful results to the agency of the fleas, not only because the animals were separated by a grating, but also because he never succeeded in infecting a rat or a mouse by placing it in contact with an animal inoculated in the laboratory and free from fleas. In one case the body of a rat dead of spontaneous plague at Karachi, and freed from fleas, was left for 24 hours in a cage containing 7 healthy rats, none of which contracted plague. One would have almost expected to be told that the seven rats had devoured their dead companion, and perhaps that some of them had contracted the disease in that way. Simond cannot explain exactly how the flea infects. It is not likely that the flea's lancets can retain the infection long ; but it may be readily observed that the flea, during suction, deposits where it sits a drop of liquid dejection, and in cases where this drop is a cultivation of the plague bacillus, it may inoculate the wound made by the flea's lancets. Further researches are required as to the persistence and ultimate fate of plague bacilli in the bodies of fleas.

Experimenting with bugs, Nuttall found that they might contain virulent bacilli but, by injections of their crushed bodies into mice, that their infectiveness died out in at the most about 72 hours. When bugs containing virulent bacilli were made to bite mice, no positive result was obtained. Yamagiwa in a little sore caused in a man by a bug-bite, or said to have been so caused, found the plague bacillus. In several cases Simond thought bugs were most likely to have been the agents of infection. He considers that the transmission of the microbe by means of parasites explains most of the hitherto inexplicable points in plague-propagation. Hankin thinks it is possible that, in order to continue virulent, the microbe has to pass from the rat to another medium, the soil, or stagnant water, or perhaps the body of an insect, and thence to another rat ; but that, in any case, more research is necessary before a positive opinion can be justified.

The rôle of flies would, of course, be confined to taking up, carrying about, and depositing the virus ; but skin-piercing insects may take a more active part in the infection of man. Blood-sucking parasites can obtain blood containing the plague bacillus only from a septicæmic case, primary or secondary.

Mode of entrance of the bacillus.—It has been proved by experiment that the virus can be introduced into certain animals by the unexcoriated conjunctiva or nasal mucous membrane, by the trachea, through the intestine by feeding, through the skin by puncture. In the case of man it has been mentioned above that there is no Bombay evidence that the plague virus can obtain primary entrance by the intestine or stomach ; but the presence of local buboes in certain cases has proved that it can penetrate by the lining of the mouth and naso-pharynx. Most of the Indian observers, except Simond, consider it certain, or almost certain, that pneumonic plague is directly infectious from lungs to lungs. That the virus often gains entrance through the skin is widely believed ; but the difficulty of proving this lies in the fact that the point of entrance is not usually either suspected by the patient or marked by signs of reaction. It has been noticed above, however, that in monkeys inoculated by an infected needle there is no local irritation. And, as a matter of fact, in a number of instances, though not in a majority, points of entrance were found on the extremities, from which points plague bacilli could be obtained, a bubo also existing in the nearest gland-group above the point of inoculation. Cases in which primary skin lesions could be found were estimated by Simond for Bombay at about one in twenty, and for Formosa by Yamagiwa at about one-seventh of the total cases. It is a common opinion that those who go barefoot are more liable to become infected ; and Aoyama asserted that the Chinese, who went barefoot, had nearly always inguinal buboes, the Japanese, who wore shoes, almost always axillary buboes. But Wilm pointed out that the 300 English

soldiers engaged in plague operations at Hongkong worked with their hands, while their legs and feet were protected by clothing, and yet the ten affected had mostly inguinal buboes. Simond gives a table of 61 cases in which primary lesions (phlyctenules) were observed with buboes corresponding. It shows that 51 primary lesions were in the skin of the lower extremity, 43 of them about the foot or ankle, and 19 of them on the dorsum of the foot; and Simond points out that they occurred on places where the skin is thin and delicate, and as such the favourite biting-places for fleas and other parasites. Yamagiwa speaks of one patient who on admission had a small sore on the leg, said to be the result of a bug-bite, and of the finding of the bacillus in this wound. The Austrian Plague Commission, on the other hand, never found a recognisable entrance-place in the skin, and never saw any cases that they considered must have been caused by insect-punctures. They, like others, point out the usual immunity which mosquito-bitten attendants of mosquito-bitten patients enjoy. The German Commission and the Plague Research Committee draw attention to the possibility of self-inoculation in scratching the skin; and the latter say that it is not improbable that plague cultures grow in the *ghee* always present under the nails of natives who eat curry, and that it is a common custom among natives for friends to receive the sputa of the sick in their hands, and to use their hands and clothing in wiping away discharges from the patient's mouth. In opposition to the common view that plague enters by little wounds already existing on the extremities, McCabe Dallas shows that there was an old belief that the presence of open wounds was protective against the plague (General Gatacre's Report, page 96). And it has been mentioned above that Simond failed to inoculate a monkey by a small open wound on the foot. But it is a matter of common knowledge that a wound inoculated at the time it is made is much more dangerous than an older wound placed in contact with a virus. Since the classical cases of Aoyama and Ischigani at Hongkong, several self-inoculations by accidental puncture at *post-mortem* examinations have occurred in India. Cases are mentioned by Thomson (Gatacre's Report), Jennings (Campbell's Report), Simond (the case of Sticker), Weir (the case of Sticker), Clemow, Prall, Green; some doubt, however, resting upon the diagnosis of the two cases reported by Green. There may be other Indian cases on record, and it is possible that a case may have been counted twice from having been reported by two different writers. With reference to such puncture cases it has been customary to say that some doubt must remain as to the reality of the inoculation because plague was prevailing at the time. But as the symptoms appeared within three days of the apparent inoculation, and as appropriate local buboes formed, the doubt here appears to be too scrupulous. Netter and also Manson give some account of some inoculation and other experiments on human beings in Egypt in the beginning of the century. The only case of laboratory infection known is that of Vienna, and both the original and the succeeding cases appear to have been of the primary pneumonic form.

Incubation-time.—So far as is known, it seems pretty certain that in the case of men and monkeys direct inoculation through the skin is followed by symptoms within 3 days; and there is reason to believe that with pulmonary infection the incubation period is much the same, perhaps a little longer. There is no doubt, however, that the time between contact with a sick person and the development of symptoms is often much longer. The probable explanation of such a case is that the subject did not then receive the virus into his system, but carried it away with him, and that the actual inoculation took place subsequently. He could only have carried it away upon his person or his clothes, in the form either of patients' excreta or of blood-filled parasites. It follows that if the bodies and clothing of all suspected persons be thoroughly disinfected during detention, the detention-limit of 10 days adopted by the Government of India is ample.

Propagation.—It is known that plague is propagated from man to man and from rat to rat. There is also strong evidence that it is conveyed from man to rat and from rat to man; in fact, it appears that in India the rat plays in the propagation of plague among men, if not a necessary, at least a frequent, part. It is also known that clothing may be the intermediary of infection between the sick and the hitherto healthy. In the case of plague-pneumonia the disease is probably propagated directly from lungs of man to lungs of man; and it is possible that among rats it may be conveyed from individual to individual by mucous membrane contact. But plague-pneumonia is after all a comparatively uncommon form of the disease, and the difficulty is to explain the method of propagation in the other and commoner forms. It is commonly taken for granted, as has already been mentioned, that the bacillus exists in the soil, and that barefooted men are therefore very liable to infection through casual wounds and abrasions. But, as has been shown above, there is no proof that the bacillus is a frequent inhabitant of the soil, even

of infected places; and there is something strange in the idea that large numbers of the population should have on their extremities little wounds and sores in a condition suitable for the reception of infection, and that such wounds should only admit the plague bacillus. It is well known that wounds that have reached a certain stage of healing are no more, or little more, liable to take up infection than the unbroken skin, and it is also known, not to mention the ubiquitous pyogenic cocci, that in the soil, especially if it be rich in organic material, are very commonly present, very actively pathogenic microbes, such as those of tetanus and of malignant œdema. Of all wounds the most dangerous is that made with an infected instrument, the wounding and the inoculation being simultaneous. It is imaginable that if a man has the virus under his nails or upon his fingers, and scratches himself with sufficient energy, or if the scratched surface happen to have some plague bacilli smeared upon it, or if with the freshly-scratched surface clothing defiled with the bacilli come in contact, that man shall inoculate himself with plague. Now one of the most usual causes of vigorous scratching is the presence of vegetable or animal parasites; and that is one way in which parasites may aid in the spread of the disease. But some animal parasites themselves inflict punctured wounds, and if the insect inject the bacilli into the wound, or puncture with contaminated lancets, or if the bacillus, whether by the agency of the insect itself or not, be upon the skin that is pierced, the result is likely to be plague inoculation. If, as appears, the flea of a man is ready to attack not only another man but also a rat, and the flea of the rat to attack a man, and if an infected flea can bide its time in unworn clothing, great possibilities of transmission are disclosed. This is the line which Simond takes in a reasoned and lucid paper, though the completeness of his scheme is somewhat ahead of the proved facts. His concluding words are:—The mechanism of the propagation of plague comprehends the transport of the virus by rats and by men; its transmission from rat to rat, from man to man, from man to rat, and from rat to man, by parasites. The measures of prophylaxis must, therefore, be directed methodically against each of these three factors: parasites, men, rats.

Conclusions.—Plague is a communicable fever, the virus of which is a bacillus. In a certain small proportion of cases the bacillus enters by the lungs, but for India its entrance by the intestine has not yet been proved. In the majority of cases it appears to enter through the skin, but the mechanism of this entry has not yet been absolutely demonstrated. There is, however, sufficient suspicion attaching to the possible rôle of insects as not only to justify but to call for further research.

History of Plague in India.—The first trustworthy information of the occurrence of plague in India dates from the year 1812, when an epidemic broke out in Cutch and spread into Gujarat and Sind. In 1828–29 a disease absolutely like the Pali plague is reported to have been prevalent at Hansi in the district of Hissar in the Punjab. In 1836 another epidemic broke out at Pali in the Marwar State of Rajputana, and spread over a considerable area causing great loss of life. Along with these isolated outbreaks there exists an endemic centre of plague on the southern slopes of the Himalayas in the districts of British Garhwal and Kumaun. The existence of this centre can be traced back with certainty to the year 1823, and it has frequently since been the scene of outbreaks of varying degrees of severity. The disease is there known as Mahamari.

Koch states that plague is also endemic in Uganda, a part of Africa which is now in touch with India, owing to the employment there of natives of India for military and other purposes.

Plague in India in 1897.—During 1897 the plague continued to spread from Bombay, both creepingly and by springs, the most notable instances of the latter mode of extension being the infection of Karachi, Khandraoni, the Hardwar Union, and the Jullundur and Hoshiarpur districts. While the plague spread gradually from the Bombay and Karachi centres, it at the same time sent out long streamers of exported cases along the Indian lines of communication by land and sea. The extremes for indigenous cases were North Sind, the Punjab, the North-Western Provinces, Hyderabad (?), Belgam, Hubli, and Goa; while imported cases occurred as far apart as Baluchistan, Kashmir, Madras, Hyderabad, and south-west of Hubli.

Plague in Bombay City.—In the beginning of December 1896 there had been a large rise in the amount of plague, and this rise continued progressively until the end of the month. Throughout January 1897, the high figure was maintained, and a further rise

occurred at the end of that month. February saw the height of the epidemic. During March the disease began rapidly to decline, and the epidemic waned steadily throughout April, May, June, and the first-half of July. From the middle of July began the recrudescence, the second great culmination being reached in February and March 1898. The following table is derived from the reports for 1896 and for 1897 of the Bombay Municipal Health Officer:—

Months.	Number of attacks.	Number of deaths.	Percentage.
September 1896	135	79	58·51
October „	406	313	77·09
November „	339	273	80·53
December „	1,664	1,271	76·38
Total ...	2,544	1,936	76·10
January 1897	2,537	2,110	83·1
February „	3,532	3,349	94·8
March „	2,694	2,424	89·9
April „	1,866	1,309	70·1
May „	448	345	77·0
June „	202	104	51·4
July „	72	42	58·3
August „	124	72	58·0
September „	247	171	69·2
October „	290	180	62·2
November „	378	254	67·1
December „	924	643	69·5
Total ...	13,314	11,003	82·6

The highest mortality in Bombay from plague occurred in the suburbs, in the districts of Mahim, Sion, Kamathipura, Parel, Sewri, and Byculla. A lower mortality occurred from plague in the surface-crowded portions of the city than in the suburbs, the explanation being, in the opinion of the health officer, the difference in ventilation. The *chawls* in which the poor classes live have often a gully on one side, and into this gully windows open. In consequence of this, there is more air circulation in the rooms in which they live, even in *chawls*, than in the central and dark rooms in the old-shaped buildings in the suburbs, although these buildings may be in the fields or surrounded by open spaces. The validity of this explanation is decidedly doubtful. Thus, the Plague Committee's Report for 1897–98 states that in Mandvi the plague chiefly occurred in large well-built houses, to few of which on the score of want either of light or of air could objection be taken. In giving the following table for 1897 the Municipal Health Officer mentions that the mortality in some classes cannot be accepted as correct, not only from concealment of cases, but also from imperfect recognition of the disease:—

Classes.	Population by census of 1891.	Number of deaths.	Death-rate per 1,000 of population.
Jains	25,225	373	14·78
Brahmins	37,982	397	10·45
Lingaets	784	26	33·16
Bhatias	7,891	59	7·47
Hindus of other castes	451,465	7,172	15·88
Hindus, low caste	45,169	1,084	23·99
Musalmans	155,101	846	5·45
Parsees	47,458	357	7·52
Jews	5,021	30	5·97
Native Christians	29,712	580	19·52
Eurasians	4,330	42	9·69
Europeans...	11,290	20	1·77
Negro-Africans	146	4	27·39
Buddhists	190	—	—
Other and unknown castes	—	13	—
Total ...	821,764	11,003	13·39

The most correct of the above statistics seem to be those of the Europeans, the Brahmins, and the Parsees. In habitations the number of deaths was generally lowest in the highest rooms of the highest buildings. Such as they are. the figures indicate that the mortality was greater among males than among females, the greatest among males between 35 and 40 years of age. According to the health officer, the experience of 1896 was repeated, in that cases in buildings were generally preceded by the occurrence of the disease among rats, and that the rats appeared almost always to travel from south to north and from east to west, and to infect one side of a street first and then the other, and that plague seemed to stick to places presenting favourable hiding and feeding places for rats, and that measures which, even unintentionally, resulted in the closure of rat-holes and the demolition of rat-homes, were of use in preventing recrudescence of plague in buildings. Just before the rise of the plague curve in July the city had been suddenly crowded by the arrival of about 300,000 or 400,000 immigrants from the mofussil, most of them in search of work. Labour was scarce, and the price of grain very high. Thus many infected or insanitary houses which had been declared unfit for human habitation were unavoidably reoccupied.

It was noticed that the first onset of the disease was rarely rapid in any locality. Isolated, imported and, perhaps, endemic cases occurred from time to time, followed by one or more small groups of endemic cases. Then the disease, having obtained a footing in the locality began to spread, and soon increased with rapidity and virulence, until the place became thoroughly infected. It was also noticed that infection appeared to spread from house to house, neighbouring houses forming groups in which many cases occurred. The infection was hardly ever found at all evenly distributed over the locality.

The origin of the outbreak remains unknown, but, as stated on page 149 of the report for 1896, the suspicion which points to China is the strongest.

Bombay Mofussil.—The figures shown in the Table on page 189 are from returns received in the office of the Sanitary Commissioner for the Government of Bombay, and "do not tally with returns elsewhere published." It is known that these and all other published figures on the subject are inaccurate, and that they err on the side of defect. On page 92 an attempt is made to estimate the amount of the defect, and reasons are there given for believing that it is very great. The following are the districts in the case of which the Sanitary Commissioner mentions the number of towns attacked :—

Districts.	Number of towns and villages affected with plague.
Khándesh	11
Nasik	60
Thána	96
Poona	119
Sholápur	69
Satára	194
Ratnágiri	10
Belgam	6
Karáchi	47
Hyderabad...	23
Shikárpur	42

Several maps have been published showing in a general way the extent of the epidemic. At the end of 1896 plague had not appeared in the districts of Nasik, Satara, Ratnagiri, Belgam, Dharwar, Bijapur, Kanara, Panch Mahals, Thar and Parkar, and Jacobabad. Indigenous cases had been reported in Bombay City, Ahmedabad, Karachi, Bandra, and Bhiwndi towns, and in one village of the Kolaba Collectorate. In Ahmedabad Town the local cases (two in number) were reported at the very beginning of the outbreak there, but the rest were imported. Imported cases only had been reported as occurring in the collectorates of Khandesh, Ahmednagar, Poona, Sholapur, Surat, Broach, Kaira, Hyderabad, and Shikarpur. In January 1897, cases occurred in the districts of Nasik, Satara, Ratnagiri, and Belgam. In February a case occurred in the Thar and Parkar district, and in March two cases in the Jacobabad circle. The first case reported in the Dharwar district was in October, and in the Bijapur district in November. The districts of Kanara and the Panch Mahals alone returned no cases of plague during the year, and the districts of Khandesh, Ratnagiri, Dharwar, Bijapur, Broach, Kaira, Thar and Parkar,

and Jacobabad were but lightly visited. The rise in Khandesh in December was due to the affection of the town of Jalgaon. The Collector of Thana, Mr. Logan, writes :—

" There has not been a single instance in this district where there is even a remote suspicion that " the plague had a spontaneous origin. In practically every case infection can be traced either to a " stranger from an infected place or to a local resident who visited an infected place. . . . There can " be no doubt that the Thana plague entered every place by the agency of persons, clothes, or rats, " which had become infected elsewhere. . . . The plague adhered to the railway, and it almost " confined itself to the area traversed by the local trains, the limits of which are respectively Virar " and Kalyan. . . . That this plague was essentially a *bania* or trading class plague sufficiently " explains why it went further along the Bombay, Baroda and Central India than the Great Indian " Peninsula, the former being the line by which Gujaratis naturally fly. . . . The fact that the interior " of the district escaped scatheless is due, in my opinion, not to its being dry, though that may be " generally true, but to the fact that, firstly, the small villages of the Kunbis offered little accommo- " dation to fugitives from the towns, and, secondly, that owing to a printed proclamation from this " office to every village, the villagers exercised a strict quarantine against all strangers. . . . The " intensity of the plague appears also to have borne no perceptible ratio to general sanitary conditions. " . . . The only satisfactory explanation of the intensity is the liability to infection by a constant " stream of immigration, *minus* promptness and vigour in segregation. Given accommodation for " high caste natives and easy distance for Bombay, infection was everywhere a certainty ; and the " degree of it depended, I should say, almost entirely on the degree of efficiency in the machinery for " stopping the spread of infection."

Writing about the same district Surgeon-Major Anderson, the Deputy Sanitary Commissioner, says :—

" With regard to the mode of conveyance of bubonic plague from place to place, it would appear " that towns and villages remote from an infected centre become infected by human intercourse, while " contiguous places frequently become infected by rats carrying and propagating the disease. . . . In " some instances we find the disease introduced by persons themselves in good health coming from an " infected locality ; and in some of these cases rats died in the houses after the arrival of the people " from Bombay, and before the persons living in the house were attacked."

In the Kolaba district the cases as a rule occurred at coast towns or villages easily reached from the sea-board, and were introduced from Bombay. The Ahmednagar district suffered from famine and plague, the Sholapur district from famine followed by plague. In the Ratnagiri district the villages affected were all near or upon the coast as in the case of Kolaba referred to above.

Plague was first detected in Karachi city early in the month of December 1896. Up to the termination of that year 63 cases and 59 deaths from plague had been reported. These cases were apparently all of local origin, the most careful inquiries having failed to discover the original case or cases importing the disease. At this period the remainder of the Sind Province, with the exception of Kandiaro and Shikarpur, into which towns cases had been imported, was free from the disease. During the year 1897 plague gradually spread along the main lines of communication ; and it was not until the 16th August 1897 that Sind was declared to be entirely free from the disease. During this period 6.057 cases and 4,770 deaths had been reported in the province. Afterwards, however, a second outbreak occurred in Kotri town, the first case being reported on the 28th October 1897. The origin of the outbreak was stated to be unknown ; but the Sanitary Commissioner thinks it probable that the disease was re-imported into the town from an infected area outside the province. Up to the end of the year, 93 cases and 64 deaths had been reported. The last case in Karachi town was reported on the 27th July 1897, the last case in the rest of the Karachi district on the 26th May 1897. One account gives the total for the city of Karachi as 4,086 cases and 3,301 deaths in 1897.

North-Western Provinces and Oudh.—Fifteen cases of plague, other than those occurring in the Hardwar Union, were reported in these provinces in 1897. Of these, eight occurred in large cities. Precautionary measures were taken, and no secondary cases followed. Only seven cases were reported from the districts, but it is quite possible that others occurred of which intimation was not given. From inquiries made by him while on tour the local Sanitary Commissioner is inclined to think that the extensive circulation of information as to the symptoms of plague and the action to be taken may have led to the adoption of the proper procedure of isolating the sufferer in some cases where no report was made of the incident. Interest principally centres round the outbreaks in the Hardwar Union. On the 8th of April the dead body of a woman was seen by the Civil Surgeon of Saharanpur and the Sanitary Commissioner at Hardwar. They arrived at the conclusion that it was a case of plague, and took action accordingly. The deceased had only occupied the hut for two days, and on searching the pilgrim lodging-house from which she had come a woman was found recovering from a severe illness and with a suppurating bubo in the groin. It was a time of much anxiety, inasmuch as the

great fair was in progress, and nearly 200,000 pilgrims were collected in the town. However, all passed off well, and the great collection dispersed without disseminating the disease. Subsequent inquiries led to the conclusion that the disease had been introduced a short time before by pilgrims from Sind. On a thorough examination of the houses in the neighbourhood of the pilgrim lodging-house above referred to three more cases were discovered, and up to the 22nd April the total number was eight. Between the 22nd April and the 16th May no cases were reported; but on the 16th May a *pujari* who had visited, and probably slept in, the infected area, died of plague, and afterwards nine more cases occurred, the last on the 8th June. Eighteen cases in all occurred. The first seven cases occurred within 130 yards of one another in a definite portion of the town, the evacuation of which for purposes of disinfection was possible. Within a mile and a half of Hardwar is situated the town of Kankhal, with some 6,000 inhabitants, and much communication exists between the two centres of population. About the middle of June an unusual mortality among rats was observed at Kankhal, and the government bacteriologist discovered the plague bacillus in some of them. Steps were taken to obviate the threatened danger, and it was at first hoped with success. But in the first week of September the special plague medical officer, who had been left in charge of this town, had his suspicions aroused that all was not right, and on the 16th of the month an undoubted case of plague was reported. About the middle of October an alarming development was the occurrence of the disease among the hordes of monkeys which infest this town. Subsequently Messrs. Hankin and Haffkine found the bacillus in the dead bodies of some, though most of the examinations gave negative results. In the case of the human inhabitants of Kankhal the diagnosis of plague was also confirmed by bacteriological examination. In all 64 cases occurred, distributed over the greater part of the town, but so grouped together as to form definite *foci* of the disease, which were made the basis of the proceedings taken for the evacuation of infected localities. By the third week in December the outbreak was practically at an end, and early in February 1898, the town having been disinfected, the people were permitted to return to their houses. Meanwhile the disease had appeared in certain villages in the vicinity; but it was not till the 9th of January 1898 that it broke forth in the town of Jawalapur, $2\frac{1}{2}$ miles distant, and with 15,000 inhabitants.

Punjab.—The origin of the plague in the Punjab is involved in some obscurity. The following account is principally derived from the Sanitary Commissioner's report:—

"In February a Brahmin named Ram Saran left Khatkar Kalán, a village of 1,200 inhabitants in "the Nawashahr tahsil of the Jullundur district, for the purpose of making a pilgrimage to Hardwar, "a place in which the first case of plague was discovered on the 8th of April. He returned to his "village on the 29th of April, and it is reported that he stayed one night at Rahon (another village "near Nawashahr) on his way back, and that it was here the symptoms of the disease first showed "themselves. By the time he reached his home he was very ill with high fever and delirium, and "after a few days' illness he died. The people of the village in this case apparently recognized that "he was suffering from some new form of fever, of which they had no previous experience, but it "was not reported at the time. Shortly after the death of the first case a Brahmin woman was "attacked (a relative of Ram Saran), by name Mussammat Málin, who lived near a large well situated "in this part of the village, and subsequently there were a few more cases of severe fever which "caused no anxiety to the villagers, as they were ignorant of its nature, and there was no tendency "to an epidemic. At the end of July or the beginning of August, however, rats were noticed to be "dying in a curious way in some cattle-sheds belonging to a zamindar named Hari Ram, situated not "far from the well referred to, but beyond noticing the fact it does not seem to have aroused any "suspicion whatever in the minds of the villagers, so far as has been ascertained, or if it did it was "certainly kept quite quiet.

"In September the Chamárs, who live on the west side of the village, and whose houses adjoin "those of the Brahmins living near this well, became affected. The disease then began to spread "more rapidly, and by October had taken on the characters of an epidemic, and the villagers now "realized that they had an infectious and very fatal form of disease among them. On the 14th "October four deaths took place, which thoroughly frightened them, and a report was sent to Banga "Thana, and the Hospital Assistant at the dispensary went at once to the village, and as the result of "his investigations he reported the disease as plague. The Civil Surgeon, Jullundur, then went to "the village and expressed the same opinion.

"On the morning of the 18th October the Sanitary Commissioner received a telegram from the "District Superintendent of Police to the effect that plague had appeared in Khatkar Kalán, and "immediately instructed the Deputy Sanitary Commissioner to meet him at Jullundur, and together "they visited the village on the 21st October, when the disease was officially announced as plague. "The last case at Khatkar Kalán occurred on the 4th December 1897.

"After Khatkar Kalán had been declared free of plague, cases were found in other villages, which "showed that the disease had spread, as on the 2nd November Jhandher Khurd, a village west of "Banga, and about six miles from Khatkar Kalán, was found to be affected; the Chamárs, who were "the first to be attacked, being related to the Chamárs of Khatkar Kalán. It was dealt with in the "same manner, and there were here only 29 cases and 18 deaths altogether, the last case occurring on "the 19th December, the total population of this village being 395. On November the 24th plague

" was discovered in Khán-Khána, a large village containing 2,500 inhabitants, but it is almost certain " that it was present in this village some time before it was reported by the village headmen. The " villagers at first were not inclined to leave their houses, as they hoped that segregating the sick " would be sufficient to check the disease, but a very rapid increase in the number of seizures (96) " during the following fortnight caused them to understand their danger, and in the end they asked " to be put out into camp. This was done, and by December 6th everyone was out and the village " deserted. After the evacuation of the village the disease, as elsewhere, declined, but not so rapidly " as in the other villages, a fact probably due to the firm hold of the place the disease seemed to have " obtained, as well as to the large number of persons under treatment, and to the cold weather which " made the people huddle together more than they had previously done.

" The next place the disease appeared was at a village named Berámpur in the Garhshanker tahsil " of the Hoshiárpur district, about ten miles distant from Khatkar Kalán, the outbreak being reported " on December the 11th. In this case the source of infection was distinctly traced to Khatkar Kalán, " as a sweeper's wife ran away from that village when her husband was attacked, and she subse- " quently became ill and died at Berámpur. It is reported that she escaped from Khatkar before a " proper cordon had been placed round the village, and from the investigations and inquiries subse- " quently made by the officers detailed for duty in the infected area, there seems reason for thinking " that two, or possibly three, villages were infected before it was realised that there was plague in the " district. Khatkar Khurd was found to be affected on the 28th December, and had 10 cases.

" Up to the close of the year there were altogether four villages in the Jullundur district and one in " Hoshiárpur attacked, 274 cases and 155 deaths occurring in the Jullundur villages, and 28 cases " with 20 deaths in the Hoshiárpur one. The disease thus spread slowly in the province, just as it " has done in Bombay and elsewhere, and it was only in the month of February 1898, after heavy " rain had fallen, that it made a sudden rise, spreading more rapidly to other villages with increase " of cases.

" 'There seems to be no doubt,' says the Deputy Sanitary Commissioner, 'in the minds of the " 'villagers that Ram Saran brought plague into their midst, and the impression is strengthened when " 'we remember that there was plague at the time at Hardwar, where the man had been. The " 'disease was at first confined to the Brahmins, to which caste he belonged, and there seems to have " 'been a regular sequence of cases from Ram Saran to the Chamárs who were found with the " 'disease on them when we arrived. Further evidence was found when the people evacuated the " 'village between October 24th and 26th.

" 'Up to this time none of the Rawals had been attacked. They lived in a separate 'patti' or " 'section of the village, cut off from the rest, and had quite a different entrance to the Brahmins. " 'But after they got out a woman named Barkat, wife of Nabbu, was attacked and died. As it was " 'impossible for the infection to have arisen in the new healthy camp, the inference was that she " 'became infected from the village. On going to her house, which lay at the very end of a long *cul* " '*de sac*, we were surprised to find that it adjoined, back-to-back, Ram Saran's house. In fact the " 'two houses were under the same roof. The Rawal family had no connection whatever with the " 'Brahmins. This infection of houses adjoining others in which plague has occurred is so common " 'that towards the end of the epidemic in the Banga district we made special arrangements for the " 'disinfection of all houses surrounding, and especially those back-to-back to 'infected' houses.' " 'The agency of communication is probably rats. But whatever the agency may be, the fact remains " 'that houses touching infected houses, although, as in this case, having their entrances in different " 'streets and occupied by people totally different in caste and habits, are especially liable to infection."

After having found some further evidence the Deputy Sanitary Commissioner concludes:—

" In short, all Ram Saran's surroundings seem to have been ultimately attacked."

In reviewing the evidence of the whole provincial epidemic, the Deputy Sanitary Commissioner thinks that it is pretty clear that human agency is the chief cause for the spread of the disease from village to village, and that any means which stops or hinders people from leaving an infected locality will also tend to prevent or retard the spread of the disease. There were also facts to show that, though it may not be a common mode of infection, rats may sometimes carry infection from one village to another. On the other hand, facts indicated that in the spread of plague *within* a village, though human intercourse was an important factor, rats played an equally important part; and that, after a village had been evacuated by its human inhabitants, a continuance of the epidemic among the rats remaining behind might lead to a more widespread infection of houses than existed before the evacuation. In the Punjab in 1897 there were reported 312 cases and 179 deaths, of which 302 and 175 belonged to Jullundur and Hoshiárpur, and the others were scattered imported cases.

Madras Presidency.—A racing party that had visited Poona was affected. A case of plague from amongst them was taken from the train at Guntakal and another at Arkonam. A third case underwent incubation in Madras whilst on the observation list. He died of the disease. In their eagerness for ascertaining the conditions in this—to them new—disease, a *post-mortem* was conducted by two medical officers; one had an abrasion on his hand, and was duly affected with symptoms indistinguishable (*see* above under "Mode of entrance of the bacillus") from plague; an attendant pricked his hand during the *post-mortem*, and died of this disease. This menial absconded from the hospital, but was luckily traced by the health officer. Under the system of observation in force the whole of the persons connected with the outbreak were readily traced and carefully supervised.

The man received at Arkonam ultimately recovered. Some cases in this presidency reported as probably plague, turned out on investigation to be instances of anthrax in the human being.

Gwalior.—The outbreak in the village of Khandraoni affords a typical and well-defined instance of the diffusion of the disease by human individuals. Khandraoni is a small village situated in the Gwalior State and distant about twenty miles from Jhansi. The population in July 1896 was 558. For some years past several of the inhabitants of Khandraoni had been in the habit of going to Bombay and taking service there, revisiting their village at intervals; among these were two Brahmins, Bindraban and Khoobi, the former being one of the headmen of the village. These two Brahmins came from Bombay to Khandraoni in January in 1897, at a time when the epidemic was virulent in Bombay. They travelled straight from one place to the other and arrived at Khandraoni on the 9th of the month. On leaving Bombay Bindraban was suffering from fever, and Khoobi attended him on the way, bringing him to Jhansi by rail and from there, in a country cart, to Khandraoni, where he died five days after his arrival. Two days after Bindraban's death, Khoobi fell ill and died in three days, and almost a week after his death a native doctor of the village, who attended the two Brahmins, was attacked with fever and died, and at the same time a second native doctor, who came from another place to treat the first doctor, also succumbed to the disease. The plague then gradually spread amongst the inhabitants of the village, and by the 18th March, 59* seizures had occurred, of which 47* had proved fatal.

Garhwal.—The last outbreak in Garhwal, which occurred in the spring of 1897, occasioned particular notice and anxiety, as it was contemporaneous with the worst period of the Bombay plague. The locality was a small village near Okhimath on the main road of pilgrimage from Hardwar to Kedarnath, and some 20 miles distant from the latter place, which was the scene of the 1823 outbreak.

At the commencement of the attack some of the inhabitants, following the usual practice in such cases, left the village, which was very small, remote, and inaccessible, and thus escaped infection. Only four or five families remained, most of the members of which died of the disease. There were 17 deaths in all.

Plague elsewhere.—Most of the districts or places where plague occurred in 1897 have already been mentioned, and the following completes the list, with the exception of the Portuguese possessions of Daman and Goa, in the former of which the outbreak was severe:—

YEAR.	Cutch.		Hyderabad.		Central Provinces.		Rajputana.		Baluchistan.		Kashmir.		Central India, excluding Khandraoni.	
	* Cases.	Deaths.	‡ Cases.	Deaths.	† Cases.	Deaths.	† Cases.	Deaths.	† Cases.	Deaths.	† Cases.	Deaths.	Cases.	Deaths.
1897...	6,653	5,709	24	8	16	11	51	44	2	1	1	—	21	11

* Imported and Indigenous. † Imported only. ‡ Imported and perhaps also indigenous.

The first case reported to have been landed from Bombay at Mandvi, the principal seaport of Cutch, was on the 3rd of October 1896, but indigenous cases were not reported there till the 9th June 1897. The first place to suffer to any extent from indigenous cases was Rawapur, which was infected from Karachi by a dirzi, who gave the disease to 11 of his relatives, all of whom died. Mandvi is in direct and constant communication with Bombay and Karachi; and most of the other villages of Cutch affected at first were within easy distance from Mandvi and the coast. The disease does not appear to have taken root in every place to which it was imported. The epidemic reached its acme in May, and then declined rapidly; but there was a recrudescence in August and September, and cases continued to occur up till the end of the year. It is said that vegetarians were more affected than meat-eaters.

* Now given as 74 cases and 52 deaths.

Conclusions.—In its long distance marches plague seems to have spread along the lines of communications—coasting steamers, railways, roads, rivers—and in this case man, in person or clothes, was the agent of diffusion. Between the houses and streets of a town or village, and even between closely neighbouring villages, the disease was often carried by rats also.

Measures for India.—At the end of January, when the plague had, in spite of all precautions, taken a firm hold of Bombay, when it had become epidemic in Karachi, and when it had begun to spread to Poona, Ahmedabad, and other places, it became evident that the ordinary provisions of the law were not sufficient to enable the local authorities to enforce all the measures necessary for grappling with the disease where it already existed, and for preventing its spread to other districts, provinces, and countries. Accordingly, the Government of India determined, having regard to the high mortality resulting from the plague, the persistence of the disease in Bombay and Karachi, the apprehension that it might spread and become epidemic in other places, the injury that was resulting to the trade of the places affected and the country at large, that it was necessary to take special powers by legislation. With this object a bill to "provide for the "better prevention of the spread of dangerous epidemic disease" was introduced in the Council of the Governor-General on the 28th January and passed into law as the Epidemic Diseases Act (III. of 1897) on the 4th February. The intention of the Government of India in passing the Act was that regulations for dealing with the epidemic should, subject to the general control of the Governor-General in Council, generally be made by the Local Governments, who, with their greater local knowledge and experience, and with their greater facilities for gauging local opinion and enlisting local sympathy, were in the best position to devise regulations to meet the particular circumstances which had arisen and might arise in the territories under their administration. Therefore, on the day that the Act received the force of law began the issue of the necessary series of notifications conferring powers on Local Governments and Administrations. The Government of India itself found it necessary to take action under the Epidemic Diseases Act only in four classes of cases; issuing orders referring to the prohibition of the pilgrimage to Mecca, to the prohibition of emigration from India, to the temporary prohibition of the booking of railway fares to certain localities with a view to prevent the assemblage of large religious gatherings, and to the prohibition of the importation of certain articles likely to carry the seeds of infection from the Bombay Presidency to other parts of India.

The preventive measures actually adopted may be divided into the following classes:—

(1) *Measures to suppress the disease in plague centres.*—Arrangements to ascertain the existence of plague cases by compulsory report, registration at burning and burial grounds, house to house visitation, inspection of corpses, and other means; the treatment of plague patients in special hospitals constructed with a view to the segregation of the sick; the disposal of corpses in a manner calculated to prevent their breeding infection; the segregation of persons who had been living with persons suffering from plague; the evacuation of infected buildings and localities, and the accommodation of their evicted inmates in carefully-supervised health camps; the disinfection and cleansing of houses in which cases of plague had occurred; the disinfection of contaminated articles, or their destruction if they were of little value; the exposure of insanitary and infected dwellings to light and air; the demolition of insanitary and infected huts; the general disinfection and cleansing of the locality; the general improvement of drainage; and other sanitary precautions, such as the abatement of overcrowding.

(2) *Measures to prevent isolated cases establishing a fresh focus of infection.*—These were similar to those described above. They consisted mainly in the segregation of the sick, and of those who had been in contact with them; the disposal of the corpses in a safe manner; the disinfection or destruction of contaminated clothing, bedding, and other articles; the disinfection of contaminated conveyances; the evacuation of the dwellings in which cases had occurred, and their disinfection or destruction; the evacuation, if necessary, of the locality; and the adoption of general sanitary precautions.

(3) *Measures to prevent the spread of infection by persons travelling by land.*—Land quarantine was not imposed; but all persons travelling from infected localities by rail, road, or river were examined by a medical officer, who was given a wide discretion to retain under observation, in suitable and isolated shelter,

all persons considered to be likely to spread infection by reason of the symptoms, their appearance, or the state of their clothes or personal effects, and persons without a fixed abode and who were not likely to be traceable or to give information of the occurrence of plague cases amongst them. This inspection was in general carried out on departure from the infected locality or area, and on the route or at the place of destination.

The whole of India was protected against the Bombay Presidency and Sind by a series of inspection stations on the main lines of railway traffic. Arrangements were also made to keep a watch at their own homes over persons arriving from infected districts. An additional, and very necessary, precaution was the disinfection of the clothing and baggage of travellers from infected areas, which from its condition or other reasons was deemed to be dangerous. Rules were also promulgated for the disinfection of railway carriages. Precautions similar to those adopted on the railways were put in force in the case of travellers by road and by river routes.

(4) *Measures to prevent the spread of infection by persons travelling by sea.*—Vessels sailing from ports in the infected areas, and, in the case of vessels sailing for ports out of India, from other principal ports in India, were inspected before departure, and any cases of plague discovered on board were removed. Quarantine was also impressed against the infected ports at other ports in India. The original rules enforced at the ports of arrival were issued under the Quarantine Act (I. of 1870) and were similar to those enforced against Hongkong in the year 1894. Revised rules were subsequently issued under the Epidemic Diseases Act (III. of 1897), based on the regulations prescribed by the Venice Sanitary Convention of the 19th March 1897. The rules for the medical inspection of vessels before leaving port were also revised after the issue of the Convention.

(5) *Measures to prevent the spread of infection by susceptible articles.*—The importation of rags, used apparel and bedding, waste paper, and used gunny bags, from the Bombay Presidency and Sind to other parts of India was prohibited, both by land and by sea. Precautions were also taken to prevent the spread of infection by grain and other food-stuffs.

Measures in the Bombay Presidency and Sind.—A first set of general regulations under the Epidemic Diseases Act was issued by the Government of Bombay on the 20th February. A number of additions were made to the rules in the light of later experience, and the whole series was afterwards consolidated in a notification dated 29th March.

The general course pursued was, as regards preventive measures, to hinder those coming from an infected area from entering a healthy town or village, by detention at an observation camp till freedom from infection was assured, and the person and personal effects disinfected. When the disease was apprehended, or had appeared, in a town, usually a small committee with full powers supervised the whole proceedings. Otherwise in a district the collector managed the business. The town was divided into wards, each with a superintendent in charge, with suitable assistance, which comprised a searching staff, a medical staff, and a cleansing staff. The searchers, under carefully framed rules, visited the houses, and if any sick were found, the medical staff were called in to diagnose the case, which, if considered plague, was removed to hospital, the other inmates of that house being placed in a segregation camp to be disinfected and remain there for 8 or 10 days. The cleansing staff then cleaned and disinfected the infected building. In some instances in large towns, instead of searching daily, the superintendent watched the daily number of deaths, and kept a list of the sick, any suspected case being examined. If the number of deaths mounted up, the ward was searched, and, if it could be done, the people were turned out into camp. As a rule, all the houses were cleaned and opened up either by the staff or the owners, and sanitation strictly attended to. All deaths had to be reported, and, if the cause of death was not clear, a medical inspection was made. In large towns, every now and again, without warning to the people, the whole searching staff was concentrated on a given ward, a cordon having been put round to prevent ingress or egress, and the whole place rapidly and thoroughly searched with a minimum of inconvenience to the people ; and this measure was very useful in those cases in which wards had become seriously affected. Another good measure, though it could not always be put in force, was to turn the whole ward out into a camp, whilst the houses were cleaned and opened up to light and air. The evacuation of infected localities and the lodging of the inhabitants in health camps were special features of the work in Sind, and were adopted

elsewhere. In addition, at various points on the railway, inspection stations were organised, and travellers examined ; and, according to the rules in force, either only those who were sick were detained or all travellers were detained for a fixed period, disinfection of the person and effects being also carried out.

Measures in the City of Bombay.—Until the appointment of General Gatacre's Committee on the 9th March, the remedial and preventive measures were carried out by the municipal authorities of the city. That committee was directed to strive after the discovery of all cases of plague ; the treatment of all cases in hospital ; the gradual segregation, as far as possible, of the probably affected—that is, of those living in the same room with, or in close attendance on, persons suffering from plague ; but on the understanding that the social, caste, and religious usages of the people should be treated with all consideration. The city was divided by the committee into 10 districts, and these again into sub-divisions, to each being assigned an appropriate staff and plant. In addition to the death registration and report rules, the main agency employed for detecting cases of plague was the system of house-to-house visitation. When a suspicious case was found, the medical officer was called on to certify as to whether it was a case of plague or not. If the case was diagnosed as plague, the ambulance was brought to the door of the house, and the stretcher to the room of the sick person, if the width of the doorway or the incline of the doorway staircase permitted of this being done. Special attention was bestowed on the ambulances used to carry the sick to hospital, with a view to minimise the risk of the transit. A large number of well-equipped hospitals was established and maintained, and efforts were made to overcome the reluctance of the population to the hospital system by the establishment of numerous private hospitals. General Gatacre stated that the moral and practical support which the committee received from the establishment of private hospitals was invaluable, as it quelled at once the misgivings and fears entertained by the people with regard to the hospital system. In the disposal of corpses the matter principally looked to was the condition of the burial-grounds. The actual disposal of the bodies of persons who died of plague was left, as far as possible, to the relatives and friends of the deceased, who performed the last rites according to the custom of their sect, subject only to such sanitary supervision as was essential. One of the standing rules for observance in hospitals was that the body should be wrapped in a sheet soaked in solution of perchloride of mercury before being handed over to the friends of the deceased. It is to be gathered that all persons who occupied the same portion of a tenement or the same house as the sick person were compelled to vacate the room or house to allow of its disinfection, and that they were in general segregated in the neighbourhood of the hospital in which the sufferer was being treated. The disinfection of the house formed the sequel to a visit with positive results. The committee, during disinfection, invariably treated those places where rats had been known to die as plague-infected localities. In addition to the thorough treatment of single houses, large measures of cleansing and sanitary reform were continuously executed. At one time as many as five thousand special workmen were employed on these operations.

From July, in which month began the recrudescence of the plague, the work of the Plague Committee was continued under the presidency of Sir James MacNabb Campbell. The aims set before it were to keep down the death-rate, while preventing panic and trade dislocation, and to lessen the risk of a third epidemic. To lessen the risk of a third plague epidemic, in addition to the removal of the sick, the segregation of the tainted, and the cleansing of the house, special attention was paid to the construction of camps as a relief from overcrowding, to the vacation of infected and unwholesome houses, and to the introduction of an improved provision of light and air. Apart from the cleansing of streets, the flushing of gullies, and the other general preventive measures which were efficiently carried out by the Health Department, so far as pure plague operations are concerned, the main hope of a low death-rate lay in securing the removal to hospital at the earliest possible stage of the attack. The means adopted by the committee to secure the early removal of the suffering were—information, simple house-searching, and house-searching with cordons. All these were made less effective than they might have been by the action of the people in wilfully concealing cases. "Contacts," that is, those persons who had lived in the same room or house as a patient, or had been in close association with him, were treated on the same lines as plague cases. They were removed with all their belongings to a contact camp, where they passed through a complete process of disinfection, which was applied to their persons, clothes, and moveable property. If plague cases appeared among them, these again were removed to a hospital, and the same measures for elimination and disinfection were again applied to those who had been closely associated with them, and who were therefore designated "Recontacts." This process

was again repeated, if necessary, until it was found that plague had actually been dispelled; a result which was usually attained within the first week, the majority of plague cases among "contacts" occurring within the first four days. The affected houses were treated by the several agencies of fire, disinfection, ventilation, and exposure to sunlight and air. The disinfectant most used was perchloride of mercury. When many cases of plague occurred in a house, a large *chawl*, or in a group of crowded dwellings, or when the conditions of such dwellings were so insanitary as to invite outbreak of plague, the complete vacation of such dwellings, and the removal of the inhabitants together with their property to a health camp, after the "contacts" had been set apart, was a most effective mode of attack on the epidemic. Since August 1897 one chief object of the Plague Committee had been to provide abundant and healthy accommodation in camps, both for infected arrivals and for the evicted dwellers of tainted and unwholesome buildings in Bombay. Experience in previous epidemics, both in Bombay and in the mofussil, had shown that the most efficient means of keeping the plague in hand was to remove people, as much as possible, from infected areas into camps. For this reason the committee encouraged private camps in the case of the well-to-do, and constructed public camps on available open spaces in and about the city, in which to place the indigent. Besides the contact camps and the health (public and private) camps, there were also detention camps for travellers wishing to enter the city, and observation camps for travellers wishing to leave it.

As showing the activity which characterised the work of the committee in Bombay, it may be mentioned that during the six weeks before the middle of March on an average 2,951 houses were daily searched and 106 plague cases daily discovered and taken to hospital; that on an average 100 deaths out of a daily recorded plague mortality of 195 took place in hospital; that 88 "contacts" were daily placed under surveillance in camp, and about 200 (as attendants on their friends) in hospital; and that 161 infected dwellings were disinfected and 78 vacated, the bulk of them being large buildings.

Measures in Poona.—Certain measures had already been carried out; but by a resolution of the Government of Bombay of the 9th March a committee was appointed with Mr. Rand as chairman. A great difficulty for the committee was the want of labour to carry out the operations. To meet this emergency a carefully devised and systematic plan of operations was elaborated, and carried out with the assistance of volunteers from the British and native troops stationed at Poona and Kirkee. The city was divided into a number of districts to facilitate the systematic prosecution of the measures it was decided to enforce. These measures consisted mainly in the detection of cases and the removal of the sick to plague hospitals; the removal of persons who were apparently healthy, but had been exposed to plague infection, to segregation camps; the disinfection of houses and moveable property which had been exposed to infection. Five hospitals and four segregation camps were established, and military parties were constituted for the search for plague cases, the removal of the sick and the possibly infected, and the disinfection of houses. Municipal agency was employed collaterally with the military. Notwithstanding determined and embittered opposition culminating in the assassination of Mr. Rand, the operations were carried out to a successful issue. After the recrudescence of the disease in July measures generally similar were employed.

Measures in Karachi.—From the beginning of January the disease increased rapidly, and the question of the evacuation of the infected quarters was then taken up with serious attention; and when Mr. Wingate paid a visit, on the 23rd January, he found a health camp had just been occupied by 2,000 Nasarpuris, a sect of well-to-do Hindus. At the end of January the operations in progress were cleansing and disinfecting streets and lanes; vigilant house-to-house inspection; supervision of burial and burning grounds; thorough disinfection of plague-infected houses; destruction of infected clothing; burning of infected huts; preparation of large health camps, and persuasion of the inhabitants to move into them; ventilation of houses by making holes in the roof and walls. There was practically no segregation of the sick and no medical treatment. The disinfecting work had also fallen into arrears. To remedy this last important defect, supervising officers were appointed, and the lost ground was soon regained. Every house was emptied as soon as it became infected, the sick person being left with one or two attendants, and the rest of the occupants moving to camp. The house was then disinfected. By the 11th of February the arrear work in disinfecting houses had been overtaken, and the operations had been carried in advance of the plague by the cleansing

of places which had not yet been attacked. The beginning of February was also marked by the first efforts to bring medical aid to the sick, and to segregate them. By the end of February the collector reported that few cases now remained undiscovered, and hence the removal of the healthy was at once universally carried out. On the 20th March His Excellency Lord Sandhurst visited Karachi, and, after inspecting all that had been done, appointed a plague committee, with Brigadier-General T. A. Cooke as president. Details with regard to disinfection of men and their clothing and effects at the camps and to camp-control was carefully elaborated by the committee. On the 25th March the first military search party went out. It was very carefully organised and admirably managed, the civil officers accompanied by medical men taking charge of each party. The general had carefully instructed the men, and from that day forward there was no need for the slightest apprehension, either that the soldiers would not deal tenderly, or that the people would not welcome them : not a complaint was ever preferred. From this time onwards the epidemic steadily decreased, and the operations, which had been gradually and cautiously introduced, were carried to their successful termination.

Measures in the North-Western Provinces and Oudh.—Regulations were originally promulgated by the Government of the North-Western Provinces and Oudh on the 12th February 1897, but were revised and issued in their final form on the 26th March. These dealt with the duties of the various official and non-official classes of the community in the matter of prompt reporting of cases ; with the action to be taken in municipalities and cantonments, not only on the appearance of plague, but also in anticipation of the same ; and with the procedure to be adopted for watching the rail-borne traffic from infected areas. With the second part was issued a memorandum by the Sanitary Commissioner describing the symptoms of the disease, and the procedure to be adopted in villages and small towns. Directions for the disinfection of houses, furniture, &c., in localities in which plague had appeared were also issued in a separate circular from the Sanitary Commissioner.

Measures at Hardwar and Kankhal.—The first outbreak occurred at Hardwar in April, and was probably due to infection carried by pilgrims from Sind. Special arrangements were made for dealing with the large number of pilgrims expected to attend the fairs, and for preventing, if possible, the importation of plague by pilgrims coming from infected areas. In addition to the ordinary examination of railway passengers in accordance with the Epidemic Diseases Act, every passenger was examined at Pathri station close to Hardwar. Those pilgrims found to have come from infected areas were sent on to Hardwar in locked carriages, and were kept under observation on Rori island. Pilgrims coming by road were also inspected ; and the sanitary arrangements of the town and the fair-site were carefully attended to. Provision was also made for the accommodation and segregation of the sick and their relatives and attendants. A reporting agency was appointed, and is believed to have worked well. On the occurrence of the eighth case (in April) it became clear that further measures of a more stringent nature were required. The Lieutenant-Governor decided that the infected area (*i.e.*, the area in which all the cases but one had occurred) should be placed in quarantine and evacuated, the inhabitants either leaving Hardwar altogether after examination by, and with the permission of, the health officer, or removing to a camp of observation established at some distance from the town in charge of a medical officer : the names and addresses of those leaving being forwarded to the authorities of the district of destination ; that after evacuation the houses should be thoroughly cleaned and disinfected, and should not be re-occupied till declared safe ; that all dead bodies should be examined by a medical officer before burial or cremation (as a further safeguard against concealment of plague) ; and that all pilgrims to Hardwar from infected places should reside in a special camp under medical observation. Pilgrimages to the fairs in May and June were discouraged. All this time the utmost care was bestowed on the cleanliness and sanitation of the town, and the lime-washing and disinfection of the houses was carried out without intermission. But on the 16th May occurred the first of the ten cases that ended the outbreak. This led to redoubled efforts to secure the detection of cases, and to carry out all possible sanitary improvements and disinfectant measures. Mr. Hankin was recalled from Bombay for the purpose of studying the cases bacteriologically. While special attention was thus paid to Hardwar itself, the neighbouring places were not overlooked. No cases occurred after the 8th of June.

In the case of Kankhal the following precautions to prevent the transmission of the disease from infected rats to men were adopted. In the case of any house or godown in

which rats were found to be dying in unusual numbers, the house with its contents and the neighbouring drains and premises were thoroughly disinfected in the same manner as if a case of plague had occurred; any grain, sugar, raw food material found in large quantities in such houses was exposed to the sun and air for eight hours, being carefully turned over at intervals, and then locked up in a specially disinfected room for ten days before being used for food; when in small quantities, such materials were destroyed; sacks, baskets, and other receptacles were either disinfected or destroyed; the inhabitants of such houses were induced to vacate them for ten days; and a reward of two annas per head was at the same time authorised for every rat living or dead brought in. In the town of Kankhal large quantities of grain are kept; and it was a matter of great importance to prevent these stores from becoming infected through plague-stricken rats. It was settled that such stores of grain should be thoroughly aired in the sun, and the godown or store-rooms well disinfected before the grain was again replaced in them. It was considered unnecessary to issue any orders for the destruction of grain. When plague appeared in September, the methods and machinery which proved successful at Hardwar were at once brought into force. An alarming development was the occurrence of the disease among the hordes of monkeys which infest this town. As many of these animals as possible were captured by means of "*kanjars*", and kept in cages under observation until such time as they were shown to be free from disease, when they were released in the jungles at a considerable distance from the inhabited area. These measures proved successful. By the third week in December the outbreak was practically at an end, and early in February, the town having been completely disinfected, the people were permitted to return to their houses. Meanwhile the disease had appeared in certain villages in the vicinity. A special organisation for keeping an area of some 400 square miles round the original focus of the disease under close observation was at once originated, and each fresh centre of disease was dealt with as discovered. This scheme was of great value.

Measures at Khandraoni.—At Hardwar measures of segregation, evacuation, and disinfection were successful in stamping out isolated cases before they had grown into a serious epidemic. At Khandraoni similar measures carried out on a small scale in a very thorough manner were successful in arresting almost immediately an epidemic which had become virulent in the confined area of a small village. A nominal roll of the villagers having been prepared, they were divided into four classes—those families in good health among whom no cases of fever had appeared since the 9th January; those families in good health among whom cases of plague or fever had occurred since the 9th of January; those families in which there were cases convalescent from plague or fever; and those families that contained members then suffering from plague or fever. By the aid of the military, and with very strict precautions, the village was evacuated, and the four classes were separately segregated in camp, the sick being placed under medical attendance. Very thorough arrangements were made for the discipline and complete isolation of the camps, and for the supply of food, &c. No strangers were allowed to enter the village. At the time of the evacuation of the village, hay and other inflammable materials were placed in the infected houses and those in their immediate vicinity, and they were then set alight and destroyed, care being taken that nothing that could be burnt escaped. The cleaning and disinfection of the village was delayed until the place had been exposed to the disinfecting action of the sun and air for three weeks, with a view to remove any danger of the persons engaged in the operation contracting the disease. Detailed measures were taken to prevent the spread of infection to the neighbouring villages, or its importation into them from Bombay. Complete success attended the operations so carefully devised and carried out, and in a very short time the epidemic was extinct. On the day that Surgeon Lt.-Col. Crofts, I.M.S., who planned and superintended the measures described, arrived there were eleven persons ill of plague. After that date there were only four admissions to hospital, all of which occurred within ten days of the formation of the segregation camps. The village having been thoroughly cleansed and disinfected, no case of plague having occurred since the 1st April, and no deaths since the 11th, and the patients under treatment having recovered, the segregation camps were broken up on the 29th of the month. Before this was done, every man, woman, and child in the hospital camp was obliged to bathe, and to exchange the clothes he or she was wearing for new ones, which were supplied free. The hospital huts, patients' clothes, blankets, beds, and all other articles of a combustible nature were burnt; and the only things brought out of the hospital camp were money, jewellery, metal cooking utensils, and the new clothes given to the occupants.

Measures in the Punjab.—The Government of the Punjab issued two sets of general regulations on the 8th of March. The first empowered the District Magistrate to adopt the various remedial and precautionary measures which experience had shown to be necessary. The second provided mainly for the immediate report of the existence of cases of plague. With these regulations the Government of the Punjab issued a set of executive instructions prescribing the precautionary measures in detail. On the 19th of June a further set of practical instructions was issued in the form of a circular letter.

Measures at Khatkar Kalan and Khatkar Khurd.—On the 21st October, when the disease was officially announced as plague, a cordon was placed around the village, and the necessary measures were started for dealing with the epidemic. During the following week the entire population of the village was turned out into camp, and hutted in suitable grass huts within the village area. The sick were treated in hospital, while their relatives and all who had been near infected persons, were accommodated in a special camp (called "the segregation camp") within easy reach of the hospital. The remaining population was placed in another camp known as "the health camp"; the Muhammadans, Hindus, and lower castes being all in separate divisions, and arranged so that no disputes about mingling of castes should arise. The disease showed signs of abating directly the people were got into huts, and the last case occurred in this village on the 4th December. The disinfection of the village was begun on the 31st October, and completed by the beginning of December, and may be briefly described as consisting of spraying the rooms with disinfectants, removing the furniture, white-washing the walls, and making large openings in the roofs of all the houses, to allow sunlight and air to penetrate freely; while in all infected houses the entire roof was removed, and the floor dug up to a depth of three inches. On the 6th December the Rawals, who had not had a case for a month among them, began to return to the village. Other castes followed, and all the inhabitants had returned to their houses by the 27th December. The cordon, however, was not removed till the 6th January 1898, in order to allow of 10 days' observation after every one had returned to the village; and the medical officer finally examined every person, and then declared the place free of plague. Some of the cases found in other villages seem to have been imported from Khatkar Kalán before the imposition of the cordon. The cases at Khatkar Khurd were found early, and the whole village was immediately evacuated, and escaped with only ten seizures.

Measures in Garhwal.—As soon as information was received by the authorities, the villagers who had not already left were removed and segregated, the houses were burnt and orders were issued that the site, which was water-logged and insanitary, should not be re-occupied. The neighbouring villages were thoroughly cleaned. These careful precautions were successful, and the infection did not spread. The direct pilgrim route through Okhimath was kept closed during the time that the danger of infection was apprehended.

Measures in Cutch.—The measures at first ordered, such as inspection of passengers arriving by sea, segregation and treatment, inspection of travellers leaving by land, were very late of being carried out, at least with any thoroughness; and when the European and native workers arrived to carry out operations in the style of Bombay, the epidemic had already reached a great height. An experience similar to that obtained in other parts of India was that plague in the village of Kathda was completely stopped by means of total evacuation; and it was noticed at Kathda, Mandvi, and elsewhere that people living out in the open in camps were particularly healthy.

Measures elsewhere.—The above were not the only places where measures against plague had to be adopted; but as it is quite impossible within the limits of this report to give a full account of the operations carried out in all the affected localities, the method has been followed of giving an account, in necessarily very condensed narrative, of what was actually done in very widely separated parts of India. The reader will obtain a general knowledge of how the plague was combated in India, and of the general ideas underlying the operations. Those who desire more detailed information must consult the official documents referred to. Nothing has been said of the occasional active opposition of the people, and very little of their almost constant passive opposition; because in general they are matters of common knowledge, and because in detail an account of them would occupy too much space. Throughout the paragraphs above and below regarding the progress of the disease and the measures taken against it the *ipsissima verba* of the reports consulted have been freely used without quotation marks, but sentences have been transposed and rearranged wherever the interests of condensation made it convenient.

The subject of preventive inoculation or vaccination has not been touched upon here, but it is discussed at page 164.

Railway Measures.—The importance of inspecting persons travelling by rail from the seat of the plague was recognised from the outset, and arrangements were made to inspect passengers and segregate the sick, as soon as it became clear that plague had taken a hold on Bombay, and showed a tendency to spread to other places. The Government of India was totally opposed to any interference with the ordinary avocations of persons who were not sick or suspicious, and refused also to exempt special classes from the operation of the rules. It decided that the principle governing the rules was that they should apply to all classes, but that detention should be enforced only in the case of such persons as were, in the exercise of the wide discretion which should be entrusted to the responsible officer, considered suspicious. The first arrangements were made by the co-operation of the civil with the railway authorities, who were directed to take action under sections 47 and 71 of the Railways Act (IX. of 1890). On the date that the Epidemic Diseases Act (III. of 1897) was passed the Government of India telegraphed to the different Local Governments and Administrations repeating its terms, and in doing this gave special directions with regard to the inspection of railway travellers. It was stated in the telegraphic circular that it was essential that the medical inspection of travellers in trains coming from the direction of infected districts should be complete, and that this could only be effected by the removal of the passengers from the train and their inspection by a medical officer on the platform ; also that this duty should ordinarily be performed by a commissioned medical officer. The Government suggested a series of inspection stations, which was afterwards altered in communication with the Local Governments. The inspection stations decided on are shown in the map opposite this page (not reproduced). At the principal inspection stations (marked with red on the map) a thorough examination was made of through passengers, or of passengers alighting at important centres of population, as the cases might be, and all suspicious persons were detained. At the subsidiary inspection stations (uncoloured) a less thorough examination was made, but there were arrangements for the detection and removal of sick persons, and for the treatment of plague cases in isolation hospitals. Although for the purpose of devising precautions to protect the rest of India it was necessary, when plague had become epidemic in nearly every district in the Bombay Presidency and Sind, to treat the whole of the province as infected, all places in the Presidency were by no means equally infected. Whilst some towns and villages were the scene of virulent epidemics, many others escaped altogether or suffered only slightly. To protect the uninfected against the infected localities, inspections were made of railway travellers at the time of starting from infected places, during the journey, and on arrival at destinations in the Presidency, similar to the inspections instituted for the protection of other provinces. By the Bombay rules the inspecting medical officers were empowered to examine all passengers arriving by, or intending to leave by, the train, and to detain persons suffering, or suspected to be suffering, from plague, in places appointed for the purpose. Hospital accommodation was provided for plague patients, and separate accommodation was furnished for suspected persons and for the medical staff. At minor inspection stations the officers appointed for the purpose were empowered to examine all persons alighting or intending to depart, and to detain at the appointed place all persons suffering, or suspected to be suffering, from plague. Surgeon-Major-General Warburton (Officiating Sanitary Commissioner with the Government of India), who made a tour of inspection on the railways at the end of March, recorded the following notes on the inspection stations at Kalyan and Bhusawal. At Kalyan twenty scheduled trains were examined daily. The morning report showed that there were 15 persons in the observation sheds, and 19 cases in the plague sheds. From the 13th February to the 29th March 301 persons had been detained. Of these 250 were suspects. Approximately 98 of the cases detained proved to be true cases of plague. Of these 63 had died, 16 had been discharged cured, and 19 remained under treatment. Dr. Warburton was present at the inspection of three trains, and found that the inspection was carefully and properly conducted. At Bhusawal four trains, with about 700 passengers, were examined daily. There were no trains to be examined during the night. The inspection of two evening trains at which Dr. Warburton was present were carefully performed. In the segregation camp there was accommodation for 20 plague cases and 5 suspects. There were 2 cases under observation, and 3 cases recovering from plague under treatment. Eleven other cases of plague, making 14 in all, had been detected and segregated, and of these 7 had died and 4 had been discharged on recovery. To carry out these numerous inspections of large bodies of travellers a considerable staff was of course required. At four stations in the North-Western Provinces and Oudh—Jhansi, Saharanpur, Ghaziabad, and Manikpur—European medical officers examined every passenger, the passengers being paraded for the purpose. Later on the inspection station at Manikpur was removed to Sutna. In addition to these

stations, alighting passengers were examined at the nine most important stations by hospital assistants, and the same procedure was carried out at thirty-one less important centres of population by vaccinators. Subsequently the number of these stations was increased, as experience indicated the necessity. Special arrangements existed at Haldwani, Hardwar, Roorkee, and Lhaksar. To ensure that such inspections were really efficiently carried out three travelling inspectors were appointed, who moved constantly all over the railway system of the provinces, and who submitted weekly reports to the Sanitary Commissioner. Passengers from infected areas were required to give their addresses to the special police staff at the stations, and information was then forwarded to the magistrate of the district to which the traveller was proceeding. Similar systems of surveillance of passengers were adopted in other provinces also. At Khana Junction in Bengal the observation encampment was divided into three portions—the plague hospital, the contact camp, and the suspect camp; and all the arrangements for detection and segregation were very thorough. Rules for the inspection of railway traffic were also issued in the Punjab, Madras, the Central Provinces, Hyderabad, Mysore, Rajputana, Central India, and Baluchistan. Where circumstances favoured such a course, passengers sometimes endeavoured to evade inspection, and various measures were adopted by the Local Governments to prevent their efforts from succeeding. For example, the Bengal Regulations of November 1897 contain the following rule:—"In the event of a traveller "from an infected area alighting at an intermediate station with the object of obtaining a "fresh ticket, so as to conceal the fact that he comes from an infected area, the railway "police will take down his name and the number of the fresh ticket issued, and will send "information down the line, so that he may, on alighting, be placed under observation." At a number of the principal inspection stations, both within and without the Bombay Presidency, special arrangements were made for the disinfection or destruction of all suspicious baggage. The following rule promulgated by the Government of the North-Western Provinces and Oudh is similar to those enforced in other provinces:—"If "necessary, the medical officer shall himself arrange for the disinfection or destruction of "clothes, &c. In cases where it is considered necessary that the clothes or bedding, &c., "of a traveller shall be burnt, the medical officer may, if the person is poor, or for other "sufficient reason, arrange for providing other articles in their place at the expense of "Government." On the 21st of April the Government of India issued a set of instructions for the disinfection of railway carriages, to take effect over the lines of all railway administrations. The instructions provided for two classes of cases: the disinfection of carriages in which cases of plague had been detected, and the disinfection of carriages coming from the infected area, though not containing cases of plague. To guard against the dangers of pilgrimages, measures such as those already described under the head of Hardwar, or total prohibition, were had recourse to. The Government of India issued several notifications under the Epidemic Diseases Act prohibiting the sale within the Bombay Presidency of tickets to travel by railway to the scene of different fairs held in various parts of India to pilgrims and other persons intending, or believed to be intending, to go on pilgrimage to those fairs. A number of similar orders were issued in the Bombay Presidency.

Road, River, and Frontier Measures.—Precautions were also adopted to prevent the spread of the plague by other means of communication. Some examples have already been given, as under the head of Hardwar. Observation posts were established, and authority was given to the plague officials to inspect and to detain. It was also sought to obtain the co-operation of villagers, and simple instructions were issued to them for the protection by themselves of their villages. Every precaution was taken to prevent the plague infection from crossing the frontier, and thence invading Baluchistan, Afghanistan, Persia, or Russia.

Maritime Measures.—The rules already issued by Local Governments under the Quarantine Act (I. of 1870) remained in force after the passing of the Epidemic Diseases Act, and were in some cases extended and modified. But first the Government of Bombay and then the Government of Madras issued fresh quarantine rules under the Epidemic Diseases Act, and the final rules framed in accordance with the Venice Sanitary Convention were all issued under that Act. On the 6th and 10th February respectively the Government of Bombay issued rules under the Epidemic Diseases Act for the inspection of vessels sailing from the ports of Bombay and Karachi; which practically came to this, that no vessel was permitted to depart until everyone on board had been examined, and any case suspected to be plague had been removed.

The International Conference assembled at Venice on the 16th February, and the Convention was signed on the 19th March. In a circular issued by the Government of India on the 1st of June the maritime local governments were directed to revise the

quarantine rules in accordance with the Venice Convention, and this they did by degrees at different dates. In the port of Bombay the total number of vessels of all kinds inspected was 72,808 against 570 in 1896, and the total number of persons inspected was 1,313,117 against 112,278. In all 169 cases of plague were detected, 79 in incoming vessels, 71 in outgoing vessels, and 19 in vessels lying in harbour. During the earlier part of the epidemic and up till the 6th February 1897, only vessels and persons bound for European and other quarantine ports were inspected. As an exodus of the plague-stricken population of the city had set in, Government decided to have an examination of every vessel and native craft, as well as of every crew and passenger, which left Bombay by sea for anywhere. These wholesale inspections commenced on the 6th February. The organisation for the medical inspection of all vessels and persons leaving Bombay by sea has been described in a special report by Surgeon-Lieutenant-Colonel MacCartie, published as an appendix to the "Account of Plague Administration "in the Bombay Presidency from September 1896 till May 1897." The object aimed at being the prevention of the spread of plague by sea to other Indian ports, to ports outside India, and above all to Europe, with its incalculable effects on Indian commerce, no measures were spared to obtain that end, and the most characteristic feature of the inspection became its extreme strictness and searching nature. Nor was the examination confined to the persons sailing on a vessel. The vessel itself was overhauled, and a high sanitary condition insisted on. This included the opening and thorough cleansing of lascars' boxes, which were often found to contain filthy clothes and rubbish, "quite "capable of supporting the plague microbes in comfort and affluence. In fact, it would "be impossible, humanly speaking, to devise a more stringent or exhaustive examination "for the prevention of the export of plague." All ship-commanders were, in addition, advised as to periodical inspections of their crew during the voyage, and of the advantage of frequent exposure to sun and wind of lascars' clothes and kit; whilst printed instructions were sent to shipping agents for issue to commanders of vessels without medical officers, describing the symptoms of plague, and the treatment to be adopted should the disease break out on their ships. It speaks well for the measures adopted by the Bombay Government that throughout the year 1897 only one ocean-going steamer was known to have plague on board after leaving Bombay. It is impossible to tell whether cases may not have got away across the harbour or down the Indian coast by sailing craft and small coasting steamer, notwithstanding the strict system of inspection for passengers by such vessels; but, at any rate, no such cases seem to have been reported. In all cases where plague developed among people who had been rejected from a ship, a telegram was sent to the next port of arrival with a warning that a case of plague had been removed from the vessel. During the year 3,322 persons were prevented from sailing in vessels. All persons having any suspicious signs or symptoms were rejected. Inspection of incoming vessels and passengers began in April, and 39,199 persons were segregated for periods varying from 2 to 10 days.

Emigration Measures.—On the 6th March 1897 a notification was issued by the Government of India prohibiting intending emigrants from the infected areas from leaving India.

The orders issued and measures taken with regard to the pilgrimage to Mecca are mentioned at page 163.

Measures anent susceptible articles.—The transmission as merchandise of rags and other articles likely to have come into contact with persons suffering from plague was forbidden. The exportation of grain was not forbidden, but very thorough precautions were taken. Special measures were adopted to obtain immediate information of plague cases occurring in grain godowns, or in the same building as grain godowns; and the grain was either, exceptionally, destroyed, or taken out and thoroughly exposed to the sun and the air, while the godown was carefully disinfected.

Conclusions.—The maritime measures adopted were very successful in preventing the transportation of the disease to Europe. The railway and maritime measures affecting India internally had a considerable, but a much smaller, degree of success; because they could be, and were, to a certain extent evaded, because it was impossible for roads to be as well watched as railways, and because the disease had already begun to spread before appropriate measures could be inaugurated. Where, as in the case of Hardwar, Khandraoni, Khatkar Kalan, Khatkar Khurd, Kathda, &c., a small town or village had to be dealt with, and information of the presence of the disease was early received, the measures adopted—complete evacuation of the village, thorough isolation of the sick and suspected, careful treatment of the sick—were eminently successful.

In the case of the native army also (*see* Section III., paragraph 58), where the affected people were under perfect discipline and the houses, &c., were the property of Government, similar measures were equally successful. But in large towns, such as Bombay, it was otherwise. Such a town could not be completely evacuated, many cases were neither reported nor detected, the persons who had come in contact with these cases were not isolated, and very many of the sick were not treated by a medical man. In small villages the people were more in the hands of the authorities, were more simple and docile, could have things explained to them and were able to see for themselves that no harm was being done to them, and that the result was quickly good. But in the large towns, for opposite reasons, the stringent plague measures caused vague feelings of panic and strong feelings of resentment, which led to concealment of cases and refusal of medical treatment in the town itself, and to flight of sick and infected or infection-carrying people to other localities. It has even been supposed that rats, carrying infection with them, were frightened away by the vigorous use of disinfectants and other disturbing agents. All the same, Hankin produces on page 726 of his article in Volume XII. of the *Annales de l' Institut Pasteur* evidence to show that the strenuous exertions of the Bombay Plague Committee may have been productive of good as far as the city itself was concerned. One of the great lessons to be learned from Indian experience is that simple isolation of the sick and of those who have been in contact with them is of no ultimate use. Nothing short of total evacuation is certainly effectual, total evacuation involving life in fresh open air at a considerable distance from the infected locality.

Fevers.

The total number of deaths registered under the heading " fevers " rose from 4,578,944 in 1896 to 5,026,725 in 1897, and the ratio per 1,000 of population from 21·05 to 23·12. The months of greatest mortality were November, October, and December. Each of the first six months of 1897 had fewer, and each of the last six months more, deaths than the corresponding month of 1896. The increase over the previous year was specially marked in November and October. The drought which had produced famine had reduced fever, but, when the copious and well-distributed monsoon rain of 1897 arrived, fever increased.

The greatest increases were in Coorg, the Central Provinces, Assam, and the North-Western Provinces and Oudh ; and the only decrease was in Bengal. The highest district maximum death-rate was 65 in the Central Provinces, and the lowest 15 in Burma. Why in the North-Western Provinces and Oudh the urban death-rate was in 1897, and usually is, higher than the rural, has not been explained. The same relation in Bombay in 1897, is, perhaps, due to the presence of plague in some towns.

The following table may be consulted not only for this, but also for the succeeding paragraphs dealing with fevers :—

Statement showing the deaths from Fevers registered in the different Provinces by Months during the year 1897.

Province.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.		Ratio of deaths per 1,000 of population.	
													1897.	1896.	1897.	1896.

* Includes 15,637 deaths from *Kala Azar*.

Sale of Quinine at Post Offices.—In Bengal there was a decrease of 3,962 parcels of quinine sold, each parcel containing 102 five-grain pice packets. The Sanitary Commissioner considers this to be probably due to the diminished prevalence of fever; and that the sale of the drug on an extensive scale is only a question of time, the gradual increase in the number of post offices in the interior of the province, as well as the increasing knowledge on the part of the people that this cheap and efficacious remedy can be had within easy reach of their homes, being certain gradually to have the effect of increasing the distribution of quinine among the people in this way.

In Assam, excluding 100 packages supplied to the Manipur State, and 319 distributed to vaccinators, 2,181 packages were sold against 1,059 in 1896. The increase in the amount sold through post offices in the Surma Valley, in which malarial fevers were very prevalent, was considerable. Packets of quinine were advertised for sale at all post offices in the Surma and Brahmaputra Valleys, and in the Khasi and Jaintia Hills during the year; and in the beginning of the vaccinating season two packets of quinine were given to each district vaccinator, as a permanent advance, with instructions to sell as many packets as possible in the villages visited by them in the ordinary course of their duties. In the Khasi and Jaintia Hills packages were also supplied to the missionaries, who take much interest in the work.

The sale of quinine was extended to all districts of the North-Western Provinces and Oudh. But the working of the scheme in 1897 was disturbed by the necessity of largely distributing this remedy *gratis* during the severe malarial fever which prevailed in the autumn. This liberal and gratuitous distribution of quinine to the poorer classes was very useful in mitigating the effects of the widespread malaria.

No statistics of the sale of quinine in the Punjab are given, but it is mentioned that the drug was freely and gratuitously distributed. Lala Mul Chand, Officiating Civil Surgeon of Karnal, says:—

"Personally I see there is no necessity for free distribution any longer, as the people have now "become fully alive to the benefits of the prophylactic; and its purchase through the post office and "other agencies will be enhanced, if the gratis distribution be put a stop to. Of course the gratis "distribution through the district dispensaries should be continued as heretofore."

The Central Provinces, Berar, and Madras do not appear to have furnished particulars of quinine sales.

In Coorg, during the year, 807 packets were sold at the various post offices, a very encouraging increase. The sale of quinine at the rural post offices is very much appreciated by the public; and the Sanitary Commissioner regrets that it was found necessary by the Government of India to increase the price of the powders at present, as he fears it may deter the poorer classes from buying.

No sale-statistics come from Bombay or Burma; but the Sanitary Commissioner of the latter province says that the Government scheme is in its infancy, and has not yet found general favour with the people.

Bengal.—The number of deaths attributed to fevers in Bengal in 1897 was 1,679,132, as compared with 1,760,225 in 1896; and the death-rate was 23·62 against 24·77 for the preceding year, 23·32 for the five-year period, and 19·81 for the decennium 1887–96. The smaller mortality as compared with the previous year was chiefly due to the exceptional healthiness of the earlier months, January to April, the result, no doubt, of the early cessation of the rains during the previous season. The excessive mortality from fevers in the Hazaribagh district was attributed to the debilitated condition of the people from famine; and the Civil Surgeon of Faridpur calls attention to a factor in the production or encouragement of malaria that is every year gaining ground, the steeping of jute in every available pool of stagnant water. The heaviest mortality took place in the months of November, December, and August, and the lightest in February, June, and May. The first seven months and the last month of 1897 had decidedly lower, the other months decidedly higher, mortalities than the corresponding months of 1896. Two districts, Pabna and Hazaribagh, had ratios over 35 per 1,000; four, Rangpur, Dinajpur, Jalpaiguri, and Chittagong, ratios over 30; fourteen, ratios not less than 25; eleven, ratios not less than 20; ten, ratios not less than 15; four, ratios not less than 10; one, a ratio not less than 5. The rural mortality was 23·88, the urban, as usual lower, 18·60. The extremes of town mortalities were 45·12 at Bhabua, followed by four ratios over 35, and 5·07 at Jhalukati.

The 154 admissions, against 211, of the European seamen of the port of Calcutta were made up by 7 enteric fever, 91 malarial fever, and 56 simple fever. The only death was

from enteric fever. There were 47 deaths, all out of hospital except 3, among the native floating population, yielding a ratio of 1·83 per 1,000 against 1·20 in the preceding year.

Assam.—Under the heading "fevers," in which the reporting agents are apt to include all diseases wherein rise of temperature is a prominent symptom, there were, including *kala azar*, 144,307 deaths registered in Assam in 1897; and the death-rate, which was 20·18 per 1,000 in 1896, rose in 1897 to 28·74, or 10·69 per 1,000 in excess of the mean of the previous five years. Most deaths occurred in July, August, and June, and fewest in February, January, and March. The first three months of the year showed a decrease as compared with the corresponding months of 1896, all the other months an increase, which in the case of July, August, and September amounted to a doubling. Very extensive flooding, says the Sanitary Commissioner, occurred in the Goalpara and Kamrup districts, owing to the raising of the river beds by the earthquake, and it was feared that these excessive floods would increase the mortality from malarial fevers. On the whole, however, there was no increase in those two districts, and the greatest increase in the fever mortality occurred in the Cachar district, in which the disturbances produced by the earthquake were comparatively small. The highest district death-rates were those of Nowgong (41·77), where *kala azar* is very prevalent, and of Cachar (35·30), from which none was returned. Besides these, three districts had ratios not lower than 30; one a ratio not lower than 20, and three ratios not lower than 10. The rural death-rate was 28·82, or excluding the hill district, 26·18. The mean urban mortality was 24·86; and the extremes were 65·69 at Karimganj and 2·29 at Jowai.

Regarding the distribution of *kala azar* the provincial Sanitary Commissioner writes:—

"During the year 18,612 *kala azar* deaths were reported, as against 15,637 in 1896. The mortality "from this cause in the Goalpara district continues to decrease; but in the other three districts in "which the disease is prevalent, Kamrup, Darrang, and Newgong, the recorded mortality from "*kala azar* was considerably greater than it was in the previous year. In Kamrup the increase was "inconsiderable, but in Darrang and Nowgong 1,126 and 1,424 more *kala azar* deaths, respectively, "were reported than in 1896. In the Nowgong district 12,012 deaths from *kala azar* and 2,364 "from 'other fevers' were reported as against 10,588 deaths from *kala azar* and 1,905 from 'other "fevers' in 1896. As noted in last year's report, the number of deaths registered under 'other "fevers' in the Nowgong district is so much smaller than the number recorded under this heading "before *kala azar* made its appearance, that, in all probability, many deaths which in former years "would have been registered under ordinary fevers were returned in 1897 as *kala azar* . . . . . The "greatest increase in the mortality from *kala azar*, as compared with 1896, in the Kamrup district "occurred in the Barpeta town and rural circles and in the Nalbari rural circle. In the Darrang "district more deaths were registered from this cause in all registration circles than in the previous "year, and the disease appears to have gained a footing in every portion of the district. The *kala azar* "death-rate was smaller than it was in 1896 in the Samaguri registration circle, but in the rest of the "Nowgong district the mortality registered from this cause was greater than it was in the previous "year. The months of greatest prevalence of *kala azar* were June, May, and October, and the "registered mortality was smallest in February and January. In 1896 the months of maximum "prevalence of the disease were May, June, and April, and the months of minimum prevalence were "February and January. In the circles in which *kala azar* was prevalent the greatest number of "deaths was registered under 'other fevers' in May, June, and April, and the smallest number in "September and February. In 1896 the months of maximum mortality from 'other fevers' were "June, May, and July, and the mortality was smallest in April, September, and October."

North-Western Provinces and Oudh.—The number of deaths ascribed to fevers in 1897 was 1,463,716, against 1,205,964 in 1896. The death-rate was 31·21 as opposed to 25·71 in the previous year, and to the mean ratio of 24·93 for the quinquennial period antecedent to the year under review. The heaviest mortalities occurred in October, November, and December, and the lightest in June, May, and July. The mortality in each of the first six months was lower, that in each of the last six months higher, than the mortality of the corresponding months of 1896. I am inclined, says the Sanitary Commissioner, to consider that the decline in the spring was due to more food being then available, and to attribute the premature incidence of mortality in July to the fact that persons in a weakened condition succumbed to even the weaker form of the malarial poison likely to be generated so early in the rains. There is no doubt but that later in the year malarial fever was of a severe type . . . . . It is unsafe to definitely say more than that malarial fever this year was of a severe type, and that the people generally were, from a reduced condition of health, less able than usual to withstand it. Four of the districts, Bareilly, Hamirpur, Jalaun, and Agra had death ratios over 45 per 1,000; three, Pilibhit, Hardoi, and Lucknow, ratios over 40; seven, ratios not under 35; sixteen, ratios not under 30; nine, ratios not under 25; six, ratios not under 20; and three, ratios not under 15. The

rural mortality was 30·95. On the other hand, the urban death-rate was 34·61, higher than the rural, a usual provincial peculiarity never yet accounted for in the local report. The extreme town mortalities were 88·17 at Pilibhit and 14·83 at Nawabganj.

Punjab.—There was an increase in the fever mortality in the Punjab, the number of deaths having risen from 393,535 in 1896 to 422,826, and the ratio per 1,000 of population from 19·15 to 20·57. The ratio for the preceding quinquennium was 23·41. The months of greatest mortality were October, November, and December; and those of lowest mortality, February, April, and March. The first eight months had diminished mortality as compared with the corresponding months of 1896; the last four months increased mortality, the increase amounting to doubling in October, November, and December. The highest district death-rates were those of Dera Ismail Khan (40·49) and Muzaffargarh (37·99). Besides these, three districts had ratios not less than 30 per 1,000, four not less than 25, six not less than 20, eight not less than 15, seven not less than 10, and one a ratio not less than 5. The rural death-rate was 20·80; the urban, as usual, lower than the rural, 18·43; and the urban extremes, 72·61 at Khairpur, and 5·35 at Abbottabad.

Central Provinces.—In the Central Provinces the deaths from fevers numbered 389,335, or 108,575 more than in 1896; and the mortality ratio per 1,000 of population was 40·98, against 29·55 for 1896 and 23·13 for the quinquennium. The months of greatest mortality were September, August, and October, and those of least mortality, February, April, and March. Every month of the year, except February, March, and April, had more deaths than the corresponding month of 1896, about double in the case of June and July. The term "fevers," as here recorded, says the Sanitary Commissioner, is very indefinite as regards the cause of death; and much of the general mortality from a great variety of causes is included under this head. In fact, owing to the ignorance of the reporting agency, the term is frequently used to indicate the cause of death generally, and may be, and is, applied to diseases with no relation to, or connected with, specific or malarial fevers. While the term has general application as to the cause of death, the existence of a very fatal type of malarial fever in the autumn of the year in certain areas was undoubted. In some districts the mortality from actual intermittent fever was great, and in others slight . . . . . There was no evidence to indicate that, and civil surgeons were instructed to be carefully observant whether the fever prevailing in the Central Provinces was of a contagious, relapsing, or typhous type. The highest district ratios were those of Bilaspur (66·34), Balaghat (61·37), and Saugor (60·77). Besides these, one district had a ratio not less than 50 per 1,000, three districts ratios not less than 45, three not less than 40, two not less than 35, two not less than 30, four not less than 25, one not less than 20, and one not less than 5. The rural mortality was 42·08, as usual much higher than the urban, which was 29·16. The urban extremes were 136·91 at Mungeli, a town of 4,755 inhabitants in the Bilaspur district, and 7·48 at Sambalpur. Four other towns, out of the 72, had ratios over 60 per 1,000.

Berar.—The number of deaths from fevers in Berar rose to 65,611 in 1897 from 61,931 in 1896. The ratio per 1,000 of population was 23·00, against 21·78 in 1896 and against 20·0 for the quinquennium. The heaviest mortality occurred in the months of September, October, and August, and the lightest in the months of February, March, and January. The first five months of the year had fewer deaths than the corresponding months of 1896, only about half as many in the case of the first four months; while the other months had more deaths, the increase in September amounting to doubling. The feeble health and depraved condition of body of the starving poor, says the Sanitary Commissioner, rendered them peculiarly liable to succumb to any prevailing disease and to rapidly become affected by those malarial influences which usually follow in the train of the south-west monsoon. The experience of the famine year 1878 was the same. The highest district death-rates were those of Wun (30·6) and Amraoti (25·5). Two other districts had ratios over 20 per 1,000; and two, ratios over 15. The rural death-rate was 23·1, higher than the urban, which was 22·4. The extreme town mortalities were 54·1 at Wadegaon, and 4·7 at Karajgaon.

Madras.—The number of deaths recorded in Madras as due to fevers was 292,292, or 31,523 more than in the previous year; while the ratio per 1,000 of population was 8·97, against 7·97 in 1896 and against 8·1 for the quinquennium. The months of greatest

mortality were December, October, and November, and the months of least mortality February, April, and March. Each of the first five months had fewer, each of the remaining seven months more, deaths than the corresponding months of 1896. The comparative freedom in the early part of the year, says the Sanitary Commissioner, must be ascribed to the diminished soil moisture proving inimical to the propagation of the malarial germ, in consequence of the failure of the north-east monsoon of the previous year; this was followed, on access of moisture with the south-west monsoon, in the presence of a population rendered susceptible to malaria owing to diminished food-supply, by a mortality greater than normal under this head. The highest district death-rate was that of Vizagapatam (23·8); and four districts had ratios not under 15 per 1,000; four, ratios not under 10; nine, ratios not under 5; and four, ratios under 5. The rural mortality was 9·0, the urban as usual less, 8·0. The extreme town ratios were 29·7 at Kampli and 0·1 at Rajahpalaiyam; while the town of Kalahasti, with a population of 11,715, appears to have returned no fever mortality. In the case of Kurnool town, where the ratio increased from 13·5 in 1896 to 21·7 in 1897, the Sanitary Commissioner is of opinion that the probability is that the disturbance of the soil during the excavations for the water works throughout the town had much to do with the result.

Coorg.—In Coorg there were 7,182 deaths ascribed to fevers, an increase of 3,630; and the ratio per 1,000 of population was 41·50, against the 20·53 of 1896 and the 20·75 of the quinquennium. The fever mortality ratio was nearly 83 per cent. of the death-rate from all causes. The rural mortality was 42·69, and the urban as usual lower, 29·46. The highest town mortality was 39·13 at Virajendrapet, and the lowest 21·75 at Mercara. The months of maximum mortality were July, August, and June, and the months of minimum mortality, February, January, and March. Each month of the year had more deaths than the corresponding month of 1896, the increase in each month from April to November, inclusive, amounting to doubling or more than doubling.

Bombay.—The total of deaths from fevers registered in Bombay was 452,596, or 40,367 more than in 1896; and is the highest recorded in, at least, thirteen years. The ratio per 1,000 of population was 24·05, against the 21·90 of 1896 and the 21·56 of the quinquennium. The increase was, at least partly, due to the prevalence of plague. The heaviest mortality characterised the months of August, November, and October, and the lightest June, May, and December. Each of the first five months of the year had fewer, and each of the remaining months more, deaths than the corresponding month of 1896. Although famine was present, yet owing to the scanty rainfall in the latter part of the monsoon of 1896, the deaths from fever would, in all districts, except the southern and western registration districts, have been, but for plague, about equal to the numbers reported in 1896. The highest district death-rate was that of the City of Bombay (33·40); three other districts had ratios over 30 per 1,000; seven, ratios not less than 25; five, ratios not less than 20; seven, ratios not less than 15; and one, a ratio not less than 10. The rural mortality was 23·24, the urban 29·86. The unusual fact that the urban mortality was higher than the rural is probably due to the presence of plague in some towns. The town extremes were 74·88 at Kirkee and 5·67 at Deolali Cantonment.

Lower Burma.—The number of deaths registered in Lower Burma under the heading of fevers in 1897 was 51,752, as compared with 51,521 in the previous year; and the death-rate was 11·46, against the 11·41 of 1896 and the 10·75 of the quinquennium. The months of greatest mortality were December, August, and July, and those of least mortality, March, June, and May. The months of January, July, October, November, and December had more, the other months fewer, deaths than the corresponding months of 1896. That the mortality of the second half of the year is greater than that of the first is no doubt due, says the Sanitary Commissioner, to the rise of the ground water which takes place during the rains and continues for some time after they have ceased. The highest district ratio was that of Sandoway (19·10); two other districts had ratios not under 15 per 1,000; eight, ratios not under 10; and seven, ratios not under 5. The rural death-rate was 12·05, and the urban as usual less, 7·53. The Sanitary Commissioner considers that the small ratio of urban mortality is to be explained by the fact that the drainage and sanitary requirements of the towns are better attended to than is the case in the rural areas, and by the diagnosis being to some extent more trustworthy. The extreme urban ratios were 17·48 at Shwegyin and 2·25 at Shwedaung.

Dysentery and Diarrhœa.

The number of deaths attributed to dysentery and diarrhœa throughout the registration areas of India during 1897 was 403,833, an increase of 163,644 ; and the ratio per 1,000 of population was 1·86 against 1·10 in the previous year. The months of greatest mortality were August, September, and October, and those of least mortality February, January, and March. Every month of the year had more deaths than the corresponding month of 1896 ; double in September and October. The highest provincial death-rates were those of Berar and of the Central Provinces, and the lowest that of Bengal. Every province showed an increase of ratio, the increases of the Central Provinces, Berar, and Bombay being greatest. The highest maximum district death-rates were in the Central Provinces and Berar, and the lowest maximum district death rate in the Punjab. The explanations given for the increase of bowel affections are, generally, that abundant rain after drought favoured the active causes, while the lowering of bodily strength by famine produced predisposition. In all provinces the urban mortality exceeded the rural.

The following statement illustrates not only what has just been written, but also the succeeding paragraphs upon bowel complaints in the different provinces :—

Statement showing the Deaths from Dysentery and Diarrhœa registered in the different Provinces by Months during the year 1897.

Province.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.		Ratio of deaths per 1,000 of population.

Bengal.—The number of deaths registered from dysentery and diarrhœa in Bengal in 1897 was 53,822, or 5,887 more than in the preceding year ; and the ratio per 1,000 of population was 0·75, against the 0·67 of 1896 and the 0·69 of the quinquennium. The months of greatest mortality were August, September, and November, and those of least mortality, February, January, and June. Each of the first six months had fewer, and each of the last six more, deaths than the corresponding month of 1896. The increase was most marked in August and September. The returns are not regarded as quite correct, and it is believed that many cases are returned as "fevers." The somewhat larger mortality of the year, says the Sanitary Commissioner, was almost solely due to the fact that on account of the prevailing scarcity the poorer classes of the people were obliged to live on herbs, roots, leaves of trees, and other unsuitable and unwholesome food. This, as a matter of course, materially lowered their health status, and eventually brought on this disease in a serious form. Polluted water-supply also added to the virulence of the disease in many places. The highest district ratios were those of Lohardaga (4·96), Calcutta (4·72), and Puri (4·08). Besides those, two districts had ratios not less than 3 per 1,000 ; three, ratios not less than 2 ; four, ratios not less than 1 ; eleven, ratios not less than 0·5 ; twenty-one, ratios not less than 0·05 ; and two, ratios less than 0·05. The rural death-rate was 0·61, the urban, 3·50. That the urban mortality is usually the greater seems to the Sanitary Commissioner to be chiefly due to overcrowding and its

attendant evils, which are more intense in towns than in the open country, and also to the greater probability of the disease being correctly diagnosed and reported in towns. The urban extreme ratios were 13·74 at Kotrung and 0·08 at Pirojpur.

In the port of Calcutta there were 52 admissions, but no deaths, among the European seamen ; while in the native floating population there were 13 deaths, 9 of them out of hospital, or 0·50 per 1,000 of strength.

Assam.—There were 23,136 deaths registered as due to dysentery and diarrhœa in Assam in 1897, an increase of 7,132 ; and the death-rate was 4·61 per 1,000, against 3·19 the death-rate of the previous year, and against 3·06 the quinquennial mean death-rate. The months of greatest mortality were November, October, and July, and those of least mortality, February, January, and March. Each month of 1897, except January, had more deaths than the corresponding month of 1896. It is supposed that a good many cases of cholera were returned under this head in the Sibsagar district, and that the large amount of bowel complaints in the Surma Valley was due to the excessive prevalence there of malarial fevers, along with which these bowel affections frequently appear as complications. The heavy mortality from dysentery and diarrhœa in the Khasi and Jaintia Hills is stated to have been the result of the exposure to which the people were subjected after the earthquake. The highest district ratio was that of Lakhimpur (11·66), and the lowest that of Goalpara (0·79). Excluding those, three districts had ratios not under 4 per 1,000 ; and four, ratios not under 1. The rural mortality was 4·46 and the urban 11·47. The extreme town mortalities were 33·47 at Golaghat and 0·83 at Jowai.

North-Western Provinces and Oudh.—The total number of deaths ascribed to dysentery and diarrhœa in 1897 was 58,822, an increase of 17,964 ; and the death-rate was 1·25, against the 0·87 of 1896 and the 0·97 of the quinquennium. The months of heaviest mortality were March, August, and September, and those of lightest mortality December, February, and January. Each month of 1897, except December, had more deaths than the corresponding month of 1896 ; and in February, March, and April the increase amounted to doubling or more. The highest district death-rates were those of Garhwal (5·91), Banda (4·69), Fatehpur (4·39), and Jhansi (4·36). Excepting for the hill tracts, says the Sanitary Commission, which always show large ratios for these diseases, the explanation no doubt lies in the exposure necessarily attendant on the congregation of large bodies of workers on relief works. Besides those, five districts had ratios not under 3 per 1,000 ; three, ratios not under 2 ; eleven, ratios not under 1 ; six, ratios not under 0·5 ; nineteen, ratios not under 0·05. The rural death-rate was 1·05, the urban 3·99. The extreme town ratios were 46·00 at Hardoi and 0·03 at Pilibhit, but five towns returned no deaths. Fatehpur, Unao, Rae Bareli, Sandila, Kunch, and Kashipur, in order, had also high ratios. Kashipur, says the Sanitary Commissioner, is notoriously unhealthy ; in other cases the explanation probably lies in the existence of poor-houses.

Punjab.—There were 15,851 deaths attributed to these causes in the Punjab, an increase of 1,965 ; and the ratio per 1,000 of the population was 0·77, against 0·68 in the previous year and 0·83 the quinquennial mean. The heaviest mortalities occurred in the months of October, November, and September, and the lightest in February, March, and January. June and the last four months of the year had more deaths than the corresponding months of 1896. The increase was greatest in October, November, and December. The highest district death-rates were those of Hissar (2·02) and Simla (2·01) ; six districts had ratios not less than 1 per 1,000 ; thirteen, ratios not less than 0·5 ; and ten, ratios not less than 0·05. The rural mortality was 0·58, and the urban as usual greater, 2·52. Exclusive of three towns which returned no deaths, the urban extremes were 12·74 at Balabgarh and 0·13 at Patti.

Central Provinces.—The number of deaths registered under this heading in the Central Provinces was 81,092, an increase of 51,210 ; and the death-rate per 1,000 of population was 8·53, against the 3·15 of 1896 and the 2·02 of the quinquennium. The months of greatest mortality were September, August, and October, and those of least mortality, December, January, and April. Each month of 1897 saw the occurrence of more deaths than the corresponding month of 1896 ; and only in December was the increase less than twice or thrice. The exceptionally high death-rate from such causes, says the Sanitary Commissioner, clearly indicates the severity and extent of the late famine, and the distress and suffering which affected a large proportion of the population. Dysentery and diarrhœa are the specially fatal diseases of the aborigines, who, living from hand to mouth on jungle foods, suffer severely from bowel disorders, particularly in times of scarcity, and rapidly

succumb to such complaints. The highest district death-rates were those of Merwara (24·14) and of Mandla (23·12) ; one district had a ratio not under 15 per 1,000 ; five districts, ratios not under 10 ; six, ratios not under 5 ; and six, ratios not under 1. The rural death-rate was 6·99, the urban 25·16. The extreme town mortalities were 188·59 at Burha and 0·16 at Kamptee. Eight other towns out of the seventy-two had ratios over 100, two of them, Mungeli and Mandla, over 160.

Berar.—The total number of deaths registered as due to dysentery and diarrhœa in Berar in 1897 was 29,549, an increase of 11,827 ; and the death-rate was 10·36 per 1,000, as compared with 6·23 in the previous year, and with 5·8 the mean death-rate of the previous five years. The heaviest mortalities occurred in the months of September, August, and October, and the lightest in the months of February, March, and January. Each of the first five months of 1897 had fewer, and each of the other months more, deaths than the corresponding month of 1896. The increase amounted to more than doubling in August and November, and to more than trebling in September and October. The famine distress in itself, says the Sanitary Commissioner, is sufficient to account for the great increase of mortality under this head, as diarrhœa and dysentery are the usual ending in chronic starvation. It was noted at poor-houses and other centres of medical relief that as soon as the monsoon rains set in bowel complaints became rife amongst the destitute poor, a large proportion of the mortality being due to dysentery and diarrhœa. The highest district death-rate was that of Ellichpur (16·4) ; two other districts had ratios not below 10 per 1,000 ; two, ratios not below 5 ; and one a ratio below 5. The rural mortality was 10·2 ; the urban mortality 11·3 ; and the urban extremes were 27·4 at Pusad and 0·3 at Wadegaon. Seven other towns out of the 38 had ratios over 20 per 1,000.

Madras.—The total number of deaths registered under this heading in Madras in 1897 was 38,716, an increase of 13,914 ; and the death-rate was 1·19 compared with the 0·76 of 1896 and the 0·8 of the quinquenninm. The months of greatest mortality were August, September, and July, and those of least mortality, April, March, and February. Every month except December had more deaths than the corresponding month of 1896 ; and the increase in July and August nearly amounted to doubling. Seven of the districts which contributed to the excess were "formally recognised" as suffering from famine. The highest district mortalities were those of Madras (4·5), Malabar (3·3), and South Canara (3·2) ; three other districts had ratios not under 2 per 1,000 ; four, ratios not under 1 ; nine, ratios not under 0·5 ; and three, ratios not under 0·05. The rural death-rate was 1·0 ; the urban, as usual higher, 3·5. The town ratio-extremes were 8·5 at Bimlipatam, and 0·1 at several towns ; but 12 towns returned no deaths from dysentery and diarrhœa. In view of the continued presence of diarrhœa and dysentery in Coonoor, from which the death-rate in 1897 was 7·2, the Sanitary Commissioner urges upon the municipality the adoption of a sound scheme of water-supply now before it, "if it does not "wish the fame of Coonoor as a sanitarium to pass away from it for ever."

Coorg.—During 1897 the number of deaths under this heading in Coorg rose to 538 from 323 in the preceding year. The ratio of 1897 was 3·11, that of 1896, 1·87 ; and that of the quinquennium, 1·56. In June, July, and August the deaths were most, and in February, March, and December least, numerous. Each month of 1897 had more deaths than the corresponding month of 1896, double in March, nearly double in February, June, and July, and more than double in September and October. The rural mortality was 1·89, the urban, 15·54, The town extremes were 36·43 at Virajendrapet and 0·66 at Somvarpet.

Bombay.—During 1897 the number of deaths from dysentery and diarrhœa in Bombay was 85,966, an increase of 49,920 ; and the ratio per 1,000 of population was 4·57, against the 1·92 of 1896 and the 1·85 of the quinquennium. The months of greatest mortality were August, September, and July, and those of least mortality, February, January, and March. Every month of 1897 had more deaths than the corresponding month of 1896 ; and after March the increase in most cases amounted to more than double or treble. There is no doubt, says the Sanitary Commissioner, that the large rise in mortality from dysentery and diarrhœa is due to famine. In areas where the famine most prevailed the mortality is found to be the highest, and in the areas upon the fringe of the famine the death-rates are also high. The highest district death-rate was that of Sholapur (12·22) ; eight other districts had ratios not less than 5 per 1,000 ; four, ratios not less than 1 ; two, ratios not less than 0·5 ; and nine, ratios not less than 0·05. The rural death-rate was

4·48 ; the urban, as usual higher, 5·17. The urban extremes, excluding three towns that returned no deaths from the diseases in question, were 23·14 at Athni and 0·12 at Dholka.

Lower Burma.—In Lower Burma the number of deaths registered from dysentery and diarrhœa was 8,793, or 1,016 more than the number of the previous year. The ratio per 1,000 of population was 1·95 for 1897, 1·72 for 1896, and 1·59 for the quinquennium. Deaths were most numerous in July, August, and June, and least so in November, January, and October. In each month of 1897, except January, June, September, October, and November, there were more deaths than in the corresponding month of 1896, double in April, and not far from the same in February and March. Four districts had ratios not under 3 per 1,000, Toungoo having the highest ; five, ratios not under 2 ; seven, ratios not under 1 ; and two, ratios under 0·5. The rural mortality was 1·83 ; the urban, as usual greater, 2·71. Excluding three towns that returned no deaths from bowel complaints, the urban extremes were 8·43 at Ramree and 0·16 at Shwedaung.

Injuries.

The deaths recorded under "injuries" during 1897 numbered 115,947 deaths, or 23,416 more than in the preceding year. Most of the provinces participated in the increase. The ratio of mortality ranged from 0·79 in the Central Provinces to 0·22 in Mysore. The months that saw most deaths from injury were August and November ; and the maximum usually falls in the third quarter of the year.

Statement showing details of Deaths from Injuries registered in the different Provinces during the year 1897.

Province.	Population under registration.	Details of Deaths from Injuries.				Total.
		Suicide.	Wounding.	Accident.	Snake-bite or killed by wild beasts.

Total	217,396,056	12,864	57,765		25,318	115,947

All Other Causes.

The number of deaths recorded under "All Other Causes" was 1,476,672 against 1,358,260 ; and the ratio per 1,000 of population, 6·79 against 6·24. Only in Bengal, Madras, and the Punjab was there a decrease of ratio. The greatest number of cases under this heading was returned in August.

Vaccination.

The total number of vaccinations performed among the civil populations in all the provinces of India, during 1897–98, was 7,829,983, as compared with 8,019,836 in 1896–97. The decrease in the number of operations was confined to Bombay, the North-Western Provinces and Oudh, the Punjab and the Central Provinces, where the working of the department was hindered and embarrassed by the conditions arising from the presence of famine or plague or both. In the remaining provinces there was a marked increase in

the number of operations as compared with the previous year. Of the total number of operations performed, 7,209,794 were primary, of which 6,771,664, or 93·92 per cent., were successful ; and 620,189 were cases of re-vaccination, of which 399,823, or 64·47 per cent., succeeded.

Excepting in Madras, Bengal, Assam and Burma, the amount of protection afforded to the infant population was less than in 1896–97. The total number of children under one year of age successfully vaccinated was 2,815,592, against 2,903,167 in the preceding year ; the percentage protected, estimated on a hypothetical birth-rate of 40 per 1,000 of the census population, ranging from 63·4 in Berar to 17·8 in Bengal and 13·10 in Coorg. The number of children, between one year of age and six years, who were successfully vaccinated was 3,172,881, against 3,237,849 in 1896–97. The proportion of persons successfully vaccinated per 1,000 of the population was, however, greater than in the preceding year in all the provinces, except Bombay, the North-Western Provinces and Oudh, the Punjab and the Central Provinces.

The following statement shows in outline the comparative working of the Vaccination Department in the different provinces in 1896–97 and 1897–98 :—

Comparative statement of Vaccination in the different Provinces of India, excluding Ajmere-Merwara, in 1896–97 *and* 1897–98, *together with the death-rates from Small-pox during* 1896 *and* 1897.

Province.		Population.	Number of vaccinations performed.			Percentage of successful cases.		Persons successfully vaccinated per 1,000 of population.	Ratio of deaths from small-pox per 1,000 of population during the calendar years 1896 and 1897.	Average number of vaccinators employed in Department.*	Average number of operations per vaccinator.*
			Primary.	Re-vaccinations.	Total.	Primary.	Re-vaccinations.

Animal Vaccination.—The following paragraphs, which deal with the details of vaccination in the different provinces, show how rapidly bovine lymph is taking the place of humanized lymph in the protection of the masses in India. Calf lymph is used fresh—calf-to-arm, preserved in tubes without admixture, or mixed with glycerine, lanoline or vaseline.

The use of the vaseline admixture has, it seems, been confined to the Punjab. The ratio of success obtained with it was high, but the length of time it had been kept, and

the degree of temperature to which it had been exposed, are not noted; while it is observed that the proportion of cases in which the results were unknown is large.

In most provinces lanolinated lymph seems to be the favourite preparation. In Madras glycerinated and lanolinated lymph were both used, and the former was found generally to be the more efficient preparation, as the following statement indicates:—

		Glycerinated Lymph.		Lanolinated Lymph.	
		Number of cases.	Percentage of success.	Number of cases.	Percentage of success.
In districts	Primary and secondary operations.	592,203	88·5	89,806	87·1
	Revaccinations.	29,291	79·7	2,060	62·2
Operations performed by dispensary staff.	Total cases...	14,807	81·6	3,693	78·4
Operations in municipalities.	Total cases...	46,974	91·0	13,512	88·4

The bacteriology of bovine lymph has received much attention in European laboratories. Results in respect of the number and nature of the germs which may be present are conflicting, but there seems to be no doubt that glycerine destroys most, if not all, of them. Practically, however, it seems that danger is to be feared much more from dirty instruments, failure to cleanse the skin at the site of operation, and neglect of the vesicles, than from any germ likely to be found in lymph which has been carefully cultivated, collected and conserved.

Bengal.—During the official year 1897–98, the supervising staff of the Vaccination Department in Bengal comprised the Sanitary Commissioner, three Deputy Sanitary Commissioners, 48 District Civil Surgeons, 206 Native Inspectors and 14 Head Vaccinators; while the operating staff consisted of 85 Vaccinators paid by Government, 58 paid by District Boards, 245 employed by Municipalities or in connection with dispensaries, 3,240 men who are licensed to vaccinate for fees, and 1,101 Apprentices, a net decrease of 30 operators as compared with 1896–97. For the greater part of the year, however, the supervising staff were deprived of the services of two Deputy Sanitary Commissioners, as these officers had to be temporarily recalled to military duty on account of the strain on the military medical services during the disturbances on the frontier.

The aggregate number of operations performed by all agencies in the province was 2,319,536, as compared with 2,293,655 in the previous year, an increase which under all the circumstances of the province is certainly satisfactory. The increase was distributed over 27 districts, but in the remaining 22 and in Calcutta there was a decrease, which was most conspicuous in Chittagong, Shahabad, Noakhali, Dacca, Bankura, and Mymensingh. In Chittagong the decrease is attributable to the effects of the terrible cyclone which swept across the district in October 1897; and in Mymensing the falling off is ascribed to difficulty in getting about the district from the effect of the earthquake of June 1897 and floods. Elsewhere the decrease is ascribed to various general and local causes, such as the prevailing scarcity, emigration of the people and the presence of small-pox. The occurrence of small-pox, as pointed out by Major Dyson, should be a stimulus to vaccination rather than a hinderance, but in places such as the tributary States of Chota Nagpur, where the people are very ignorant, vaccination may, it appears, be entirely suspended during an outbreak of small-pox, the people refusing to be vaccinated, and preferring to rely on the performance of *pujas* to avert the disease.

The number of successful primary operations was 2,195,509, or 18,694 more than in the previous year, but the proportion of success was slightly less; in 1896–97 the percentage of operations successful was 97·91, in 1897–98 it fell to 97·87. This falling off is only apparent, being due to the inclusion as failures of cases, the results of which were unknown in calculating the ratios. The total number of re-vaccinations performed during the year was 76,443, nearly six thousand more than in 1896–97. Of these,

64·36 per cent. were successful, against 52·59 in the previous year. The high degree of success is ascribed to the re-vaccination of numerous adults in whom the protective effect of primary vaccination in infancy was disappearing.

Estimating the number of births at 40 per 1,000 of the census population, 17·8 per cent. of the infants born were protected, against 17·6 per cent. in 1896–97, 14·7 in 1895–96, and a mean of 12·8 in the three years 1892–93 to 1894–95.

No inspection was done by Deputy Sanitary Commissioners on account of their absence on duty in connection with plague and their recall to military employment. An Assistant Surgeon, who was in charge of the Western Bengal Circle during part of the year, verified 4,227 operations in Manbhum and Chota Nagpur, about ·18 per cent. of the total number of operations. The proportion inspected by Civil Surgeons fell from 9·56 in 1895–97 to 9·34. The number of cases verified by Civil Surgeons was upwards of 10,000 in five districts, as compared with four in the previous year, including Muzaffarpur and Dacca, where Major Peck and Lieutenant-Colonel Macrae each verified upwards of 15,000 operations. In nine districts, as compared with 13 in 1896–97, the numbers verified were between 10,000 and 5,000; in 29 districts between 5,000 and 1,000, and in five districts the number was less than 1,000. The percentages of inspections by District Inspectors and Sub-Inspectors rose from 38·47 and 65·34, respectively, to 40·76 and 67·44 in 1897–98.

There was no change in the method of vaccination in use in the province, but orders were about to issue prescribing three punctures in each arm instead of two. Vaccination with lymph taken direct from the calf is extending, and there was an increase, as compared with 1896–97, of 25,681 primary operations, and 5,228 re-vaccinations by this method, which is about to be introduced into all districts were the prejudices of the people are not such as to render the introduction inexpedient in the present state of public feeling on account of the measures which are necessary against plague.

As compared with the previous year, there was a slight falling off in the amount of lanoline paste manufactured at Calcutta, but there was a considerable increase at Darjeeling. Five hundred and sixty-four grains of lanoline paste were supplied to the Nipal Darbar from the Darjeeling depôt.

Assam.—The vaccination staff of the province consisted of 18 Native Inspectors, 182 paid Vaccinators, 30 licensed Vaccinators and 10 Apprentices. The number of operations performed by them rose from 250,350 in 1896–97 to 255,583, but the average number of operations per vaccinator fell from 1,103 to 1,065. Of the total, 245,381 were primary vaccinations and 10,202 were cases of re-vaccination, the percentages of success claimed being, respectively, 98·98 and 92·05, against 97·58 and 94·25 in 1896–97. These ratios, even though supported in respect of primary cases by the verifications of Civil Surgeons, are, of course, suspiciously high; and, during his tour in the Nowgong District, the Sanitary Commissioner found that, while the work was really excellent, the results in some of the comparatively small number of cases seen by him were unsuccessful.

The Chief Commissioner, writing of inspections by Civil Surgeons, observes that "there is reason to believe that in many instances the results of these inspections are "misleading, only successful cases having been brought before the Civil Surgeons for "examination." Further instructions have been issued to secure that the work done by vaccinators shall be more effectively tested in future.

There was a great increase in the number of operations performed by Civil Surgeons and subordinates attached to dispensaries, the number rising from 8,072 in 1896–97 to 17,177 in 1897–98. Of these 16,172 were primary cases, of which 97·66 per cent. proved successful, and 1,005 were re-vaccinations, of which 79·9 per cent. succeeded. The ratios of success obtained in the previous year were, respectively, 94·26 and 76,35 per cent.

The number of operations performed by tea-garden agencies was 11,154, or 5,120 less than in 1896–97. All were primary cases, and 95·88 per cent. were successful.

During the year the Compulsory Vaccination Act was introduced into the Nowgong Municipality, raising the number of towns, cantonments, &c., in which the Act is in force to 13. Notwithstanding this extension, the total number of operations performed in the areas of compulsory vaccination was less than in any of the preceding three years; the number in 1897–98 having been 3,487, against 4,152 in the previous year. Nearly six hundred notices were issued under the Act, and 25 prosecutions were instituted, but in only two instances were the defaulters punished.

The number of infants protected was 25·9 per cent. of the births, estimated at 40 per 1,000 of the census population, as compared with 20·4 in 1896–97, 20·9 in 1895–96, and 17·6 the mean of the three years 1892–93 to 1894–95.

Omitting the operations performed by the tea-garden agencies, 8·87 per cent. of the remaining operations were verified by Civil Surgeons, and 55 per cent. by Native Superintendents or other inspecting officers ; the percentage of cases found successful by the former was 98·66, and by the latter 98·14.

Inoculation continues to be practised in Sylhet, Cachar and Lakhimpur. The Civil Surgeons of Sylhet and Cachar state that no outbreak of small-pox was traced to the practice ; but the Inspector of Vaccination in Lakhimpur, who was sent to investigate an outbreak in the village of Kathalguri, " gave reasons for supposing that the outbreak took " its rise from persons who had been recently inoculated."

The working of the bovine lymph depôt at Shillong continued satisfactory, and the lymph supplied throughout the season was reported by Civil Surgeons to be of excellent quality. With the exception of 3,277 successful operations in Sylhet and 7 in Goalpara, performed by the arm-to-arm method, all the operations in the province were done with lymph prepared in Shillong. Endeavours were made at the head-quarter stations of districts to carry on vaccination with fresh calf lymph, but the attempts were abandoned on account of the difficulty in obtaining calves and of the strong prejudice of the people. The Chief Commissioner, however, believes that with the exercise of tact and perseverance these difficulties might be overcome ; but in view of the great success obtained with the preparation prepared at Shillong, the introduction of the calf-to-arm method does not seem to be necessary.

North-Western Provinces and Oudh.—The vaccination staff under the control of the Sanitary Commissioner of these provinces comprised 865 operators under the supervision of two Deputy Sanitary Commissioners, 46 Civil Surgeons and 50 Assistant Superintendents of Vaccination. Owing to the absence of a considerable number of the supervising staff and operators who were deputed to plague duty, to the lower birth-rate of the year, and to the unfitness of many children for operation due to their reduced condition on account of famine, the total number of operations fell from 1,527,308 in 1896–97 to 1,384,660 in 1897–98, and the average number performed by each vaccinator from 1,739 to 1,599. Of the total number of operations, 1,318,615 were primary and 66,045 were re-vaccinations, and the ratios of success obtained were, respectively, 93·74 and 68·20 per cent. Medical subordinates attached to dispensaries performed 297 primary operations and 48 re-vaccinations, of which 90·46 per cent. of the former and 60·00 of the latter succeeded.

The number of infants successfully vaccinated by all agencies was 551,296, or 27,094 fewer than in the previous year. About 29·23 per cent. of the infants born, estimated at 40 per 1,000 of the population, were protected during the year, against 30·7 in 1896–97, 30·2 in 1895–96, and 26·6 the average of the three years 1892–93 to 1894–95.

There was a considerable decline in the vaccination work performed in municipal towns, and the attention of Superintendents was again called to the necessity for the proper administration of the Act.

The Deputy Sanitary Commissioners and Civil Surgeons were so fully occupied with duties in connection with the prevention of plague that they had little time to devote to the inspection of vaccination, and it is satisfactory, in view of the circumstances, that they were able to verify 6·31 per cent. of the operations. Native Superintendents verified 26·98 per cent. of the operations, and found 91·74 per cent. of the cases seen by them to have been successful, against 90·92 per cent. found successful by the Deputy Sanitary Commissioners and Civil Surgeons.

The supply of lymph from the hills was generally sufficient and satisfactory. The establishment of a depôt at Muktesar had to be postponed in favour of more urgent work, but the scheme is ready and complete. The depôt at Lucknow was satisfactorily worked.

Punjab.—There was no change in the number of the supervising staff, which, as in the previous year, consisted of the Sanitary Commissioner and his deputy, 31 Civil Surgeons, 6 Divisional Inspectors, and 34 District and Native Supervisors, but the Deputy Sanitary Commissioner and some of the Civil Surgeons were absent on plague duty for a great part of the year. The operators numbered 305, against 303 in 1896–97 ; 278 employed as district vaccinators, 21 employed by the special staff and 6 in cantonments. There was a large falling off in the total number of operations performed, which aggregated 845,491, against 902,413 in the previous year. Primary operations were less by 41,304,

re-vaccinations were less by 15,618. The decrease is attributed in part to high infantile mortality, and in part to failure of lymph and carelessness of the operators, the latter cause being largely effective because of the absence of the completer supervision of former years. The decrease of primary operations was common to the district and dispensary vaccinators, by whom 553,317 and 1,241 operations were performed, as compared with 596,686 and 3,737 in 1896–97. The numbers of operations performed by the special staff and cantonment vaccinators, however, rose from 67,780 and 4,875 in the previous year to 72,031 and 5,185 in 1897–98. The Deputy Sanitary Commissioner, it must be noted, suspects that the returns furnished by the special staff have been exaggerated, as there was insufficient check on their work during the winter months. The number of re-vaccinations performed by all agencies fell off. The quality of the work, as distinguished from the quantity, improved, the percentage of success in primary cases rising from 93·22 to 94·40, and in re-vaccinations from 59·76 to 60·77. In the eight large native states which maintain their own vaccination establishments, the numbers of operations performed were 86,334 primary and 45,539 re-vaccinations, successful at the rates, respectively, of 95·47 and 50·52 per cent. Among these states the largest number of operations was performed in Patiala, where the total amounted to 98,674, with 96·18 per cent. of success in primary vaccinations and 50·16 in re-vaccinations, against 95·46 and 47·63 respectively, in 1896–97.

About 57·5 per cent. of the infants born, reckoned at 40 per 1,000 of the census population, were successfully vaccinated, as compared with 58·5 in the previous year, 58·8 in 1895–96, and 52·4 the mean of the three years 1892–93 to 1894–95.

Civil Surgeons verified 8·66 per cent. of the primary operations and 2·25 per cent. of the re-vaccinations ; Divisional Inspectors verified 17·94 per cent. of the primary cases, and 25·85 per cent. of the re-vaccinations ; and Native Supervisors inspected 61·10 and 23·73 per cent. of the primary and re-vaccination cases respectively. It is observed that in all cases the inspecting officers found a higher rate of success than had been claimed by the vaccinators. This, while at first sight satisfactory, points to the selection by the operators of cases for inspection, and to the desirability of instituting test inspections where every case in a village would be examined, and not only a selected few.

Three kinds of lymph were in use, namely, humanized lymph, fresh calf lymph, and calf lymph mixed with vaseline. Of the primary operations about 83 per cent. were performed with fresh calf lymph, 11·5 per cent. with vaseline lymph, and 5·5 per cent. with humanized lymph. The fresh calf lymph was the most efficient, no less than 99·3 per cent. of the cases in which it was used being successful. Humanized lymph came next, with 98·2 per cent. of successes. The vaseline preparation was much inferior to the other two, and operations with it succeeded at the rate of 94·3 per cent. only. Of the re-vaccinations 76 per cent. were performed with fresh calf lymph, 13 per cent. with humanized lymph, and 11 per cent. with vaseline lymph. In these cases the humanized lymph proved the most effective with 78·7 per cent. successful ; the vaseline lymph came next with 75·6 per cent. ; and was closely followed by the fresh calf lymph, with 74·8 per cent. The comparative inefficiency of the vaseline lymph in primary operations is ascribed by the Deputy Sanitary Commissioner to its often having been kept some time before it was used.

The vaseline lymph was prepared at the Amritsar depôt in the cold weather, and at the Murree depôt in the hot weather. Altogether 2,850 ten-grain tubes were sent to the districts, and in 1,349 instances the results obtained with the contents were successful. The contents of only 62 tubes, all sent out from the Murree depôt, failed ; but the results attained were unknown in a very large number of cases, especially in respect of tubes prepared at Amritsar. There was a considerable decrease in the total cost of the Department, owing to the absence for about five months of the Deputy Sanitary Commissioner.

Central Provinces.—The statistics of 1897–98 include the Native States of Sonepur and Bamra, excluded in 1896–97 in consequence of the non-receipt of returns from these States. The inspecting staff in the Central Provinces remained unchanged, and comprised 19 Civil Surgeons and 28 Native Superintendents ; but the average number of operators was 274, or 14 more than in 1896–97. The total number of operations was 384,476, or 12,560 fewer than in the previous year, and the average number performed by each vaccinator fell from 1,519 to 1,391. The falling off in numbers, although common to the British districts and Feudatory States, was confined to primary operations, and was due to the reduced birth-rate and other consequences of famine, and to the temporary withdrawal of members of the vaccination establishment for employment in connection with the famine and the prevention of plague.

Of the 306,673 operations performed in British territory, 268,271 were primary and 38,402 were re-vaccinations, the percentages of success claimed being, respectively, 96·73 and 85·84, a slight increase in the case of the former, and a very marked increase in the case of the latter, on the percentages of the previous year, which were 96·00 and 71·70. In the Feudatory States the total number of operations was 77,803, of which 65,622 were primary operations and 12,181 re-vaccinations, the ratios of success being 96·86 and 94·27 per cent., as compared with 97·20 and 96·01 in 1896-97.

There was a total decline of 2,550 operations as compared with the previous year in the work done by dispensary staffs. In British territory 10,998 primary operations and 848 re-vaccinations were done by them, the percentages of success being, respectively, 95·46 and 77·48. In the Feudatory States the number of primary operations performed by dispensary establishments was 2,319, of which 90·86 per cent. succeeded. Re-vaccination was limited to the State of Sarangarh, where 53 of 58 operations proved successful.

Estimating the birth-rate at 40 per 1,000 of the census population, the percentage of children born who were protected was 36·20, against 47·5 in 1896–97, 49·3 in 1895–96, and 52·9 the mean of the three years 1892–93 to 1894-95. It must be remembered in this connection that there has for some years past been a declining birth-rate in the Central Provinces.

As compared with the previous year, there was an improvement in the work of inspection. About 18·79 per cent. of the operations were examined by Civil Surgeons, and 55·45 per cent. by Native Superintendents, as compared with 15·78 and 50·24, respectively, in 1896–97. The percentage of success found by Civil Surgeons was 92·40, and by Native Superintendents 93·45, against 92·01 and 93·46 in the preceding year.

Fresh calf lymph, calf lymph mixed with lanoline, and humanized lymph were used. There is no considerable prejudice against the use of calf lymph in the Central Provinces, and the vast majority of the operations were performed with it, although it is not distinctly brought out in the report what numbers of cases were vaccinated with the fresh and stored calf lymph, respectively.

Berar.—The Vaccination Department under the control of the Sanitary Commissioner of Berar, comprised, as in the previous year, 44 operators under the supervision of seven Native Superintendents. The total number of operations performed was 125,289, or 5,178 more than in 1896–97, and the average number performed by each vaccinator was 2,847, against 2,729. The increase was due to re-vaccinations alone, the number of which rose from 21,717 in 1896–97 to 30,241. Primary operations numbered only 95,048, or 3,546 less than in the previous year, the falling off being satisfactorily explained by the high mortality among children. Primary operations were slightly less successful than in 1896–97, the percentage of success falling from 96·8 to 96·4; on the other hand, re-vaccinations were much more successful, the percentage rising from 20·5 to 30. Estimating the birth-rate at 40 per 1,000, about 63·4 per cent. of the infants born were protected, against 66·8 in 1896–97, 58·2 in 1895–96, and 60·9 the mean of the three years 1892-93 to 1894-95.

The Sanitary Commissioner's inspections were limited to the Amraoti District, where 99·8 of the operations verified by him were successful. Native Superintendents verified 53·1 per cent. of all the operations, or 2·7 less than in the previous year, and found successful results in 94·3 per cent. Operations seem to have been performed exclusively with calf lymph, either fresh or lanolinated.

Lieutenant-Colonel Little gives an interesting table showing the relation of vaccination to small-pox mortality in Berar since 1868–69, which, with his remarks on it, is reproduced.

Year.	Ratio per 1,000 successfully vaccinated.	Death-rate per 1,000 from small-pox.	Year.	Ratios per 1,000 successfully vaccinated.	Death-rate per 1,000 from small-pox.
1868–69	4·3	1·9	1873–74	14·5	3·8
1869–70	3·2	3·6	1874–75	21·0	·5
1870–71	7·9	·6	1875–76	24·0	·4
1871–72	13·0	·2	1876–77	31·0	·2
1872–73	16·2	3·8	1877–78	38·0	2·9
Mean ...	8·92	2·02	Mean ...	27·72	1·56

Year.	Ratio per 1,000 successfully vaccinated.	Death-rate per 1,000 from small-pox.	Year.	Ratio per 1,000 successfully vaccinated.	Death-rate per 1,000 from small-pox.
1878–79	22·3	2·7	1888–89	36·1	·3
1879–80	29·3	·03	1889–90	55·68	·7
1880–81	33·9	·02	1890–91	34·3	·2
1881–82	32·5	·08	1891–92	36·0	·01
1882–83	38·0	·1	1892–93	37·0	·02
Mean ...	31·2	·58	Mean ...	35·8	·2
1883–84	30·3	1·5	1893–94	35·0	·06
1884–85	37·0	·2	1894–95	32·2	·3
1885–86	35·3	·09	1895–96	31·8	·2
1886–87	35·6	·04	1896–97	34·5	·2
1887–88	35·2	·1	1897–98	34·7	·2
Mean ...	34·68	·38	Mean ...	33·6	·19

Beginning with the quinquennial period 1869 to 1873, it will be seen that the small-pox death-rate was 2·02 per 1,000 of population, and that in each period of five years it has steadily declined as vaccination has advanced, till for the period ending 1898 it has been 0·19 per 1,000.

It may be noted that small-pox inoculation never prevailed in Berar, and that the disease is quite as virulent amongst the unvaccinated as it ever was. There is nothing but vaccination to which this great diminution of small-pox mortality can be attributed. The above figures tend to prove the axiom that in countries where there is much vaccination and re-vaccination relatively to the population there is but little small-pox.

Madras.—The inspecting staff in Madras consisted of one Deputy Sanitary Commissioner, the District Medical Officers and 60 Deputy Inspectors. The average number of Vaccinators employed was 824, or 10 less than in 1896-97. Notwithstanding the reduction in the number of operators, the number of operations rose from 1,234,350 in the previous year to 1,258,010 in 1897–98, the average number performed by each operator rising from 1,465 to 1,508. The increase was not, however, general, but was limited to 11 districts and certain of the municipalities and cantonments. In 10 districts and in 31 municipalities there was a falling off, ascribed to a variety of causes ; among them, the prevalence of famine, the presence of cholera, failure of lymph, the opposition of the people, and the lack of help received from heads of villages.

Of the total number of operations, 1,177,100 were primary, of which 92 per cent. were successful, and 80,910 were re-vaccinations, in which the ratio of success was 81 per cent., as compared with percentages of success obtained in 1896-97 of 92·6 and 80·2 respectively. Besides the above, 13,719 operations were performed by the establishments attached to dispensaries, a slight increase of 349 over the number performed by them in the previous year. The percentages of success reached in dispensary vaccination were, however, lower than in 1896-97, having been, in primary cases, 83·5, against 88·0, and in re-vaccinations, 72·8, against 74·8.

In all, 331,297 infants under one year of age were successfully vaccinated. This is equal to about 23·23 per cent. of the births, estimated at 40 per 1,000 of the census population, as compared with 23·20 per cent. in 1896-97, 22·0 in 1895-96, and 18·6 the mean of the three years 1892–93 to 1894–95.

During the last nine months of the official year the Deputy Sanitary Commissioner was employed on duty outside the Presidency, in connection with plague, and was unable to carry out any inspection. The percentages of cases verified by Civil Surgeons and Native Superintendents and others were much the same as in the previous year, namely, 2·5 and 49·7. The ratio of success in the cases examined by Civil Surgeons was 92·3 per cent., and in those examined by the Native Superintendents 89·1, as compared with 90·8 and 89·5 per cent. found successful by these officials, respectively, in 1896–97.

Humanized lymph was not used anywhere in the Presidency. In all operations performed during the year animal lymph was used, either (*a*) fresh calf-to-arm, (*b*) stored in tubes without admixture, (*c*) mixed with glycerine and stored in tubes, and (*d*) mixed with lanoline and stored in tubes.

The results obtained with the various vaccines used in the districts, excluding dispensaries and municipalities, is shown in this statement :—

—	Number of Cases.	Percentage of Success.
(*a*) Fresh lymph	302,225	97·9
(*b*) Lymph without admixture ...	·126,683	95·9
(*c*) Glycerinated lymph...	621,494	88·1
(*d*) Lanolinated lymph	91,866	86·6

As in former years, lymph taken direct from the calf secured the best results. It will be observed that the positions held by glycerinated and lanolinated lymph have been reversed, due to a great falling off in the percentage of success obtained in 1897–98 with the latter. As compared with 1896–97, the percentage of success in operations with glycerinated lymph has fallen from 88·9 to 88·1, while the falling off with the lanolinated lymph is from 94·0 to 86·6.

Coorg.—The vaccination establishment under the control of the Civil Surgeon of the small province of Coorg consisted of an average of eight operators working under the supervision of a Native Superintendent. The total number of operations performed was 10,616, or 610 more than in 1896–97, and the average number done by each vaccinator rose from 1,112 to 1,180. Primary operations numbered 9,230, of which 95·80 succeeded; and 89·25 per cent. of 1,386 re-vaccinations were successful. Medical subordinates attached to dispensaries performed 250 primary vaccinations and 111 re-vaccinations, of which 73·60 and 32·43 per cent., respectively, succeeded.

Estimating the birth-rate at 40 per 1,000, which is, in this case, above the actual rate, only 13·10 per cent. of the infants born during the year were protected, against 18·6 in 1896–97, 17·2 in 1895–96, and 13·3, the mean of the three years 1892–93 to 1894–95. The falling off in infantile vaccination is attributable to the low birth-rate and to the exceptional insalubrity of the year, which led to the postponement of vaccination in many cases.

Calf lymph was used exclusively. About 1·55 per cent. of the cases were verified by the Civil Surgeon and 31·93 by the Native Superintendent, as compared with 1·24 and 33·41 verified by them, respectively, in 1896–97.

Bombay.—Excluding the Native States of Baroda, Cutch, Kathiawar, Palanpur and Idar, the returns from which are dealt with separately, the vaccination staff of the Bombay Presidency comprised, under the control of the Sanitary Commissioner, 5 Deputy Sanitary Commissioners, 1 Superintendent of Vaccination for the City of Bombay, 45 Inspectors of Sanitation and Vaccination, and 435 Vaccinators. The total number of operations performed was 736,409, as compared with 802,738 in the previous year, and the average number performed by each operator fell from 1,834 to 1,690. The falling off was general throughout the Presidency, and was due to the disturbing effects of famine and plague. Of the total number of operations, 675,901 were primary, 59,495 were re-vaccinations, and 1,013 were secondary operations, performed in cases in which the first operation had failed. The percentage of success in primary operations was 91·90, and in re-vaccinations 58·41, compared with percentages of 92·19 and 59·64 in 1896–97.

By dispensary establishments 3,021 operations were performed, of which 2,313 were primary, 655 re-vaccinations, and 53 secondary. The ratios of success attained were 95·98 and 69·77 per cent., against 85·67 and 76·13, respectively, in the previous year.

Estimating the births at 40 per 1,000, 55·54 per cent. of the infants born were protected, as compared with 59·1 in 1896–97, 58·0 in 1895–96, and 56·2 the mean of the three years 1892–93 to 1894–95.

The work of inspection suffered great interference from the effects of famine and plague. All the Deputy Sanitary Commissioners and many of the Inspectors were employed on plague duty during the year; moreover, owing to the absence of villagers from their homes during the famine, and the exodus from towns on account of plague, it was difficult

to find the children who had been vaccinated. The percentage of operations inspected by Deputy Sanitary Commissioners was only 1·18, and by Native Inspectors 31·79, as compared with 4·74 and 36·42 in 1896–97, and 7·03 and 37·67 in 1895–96.

Bovine lymph was used in the City of Bombay exclusively, and in selected areas elsewhere.

In the Native States of Baroda, Cutch, Kathiawar, Palanpur and Idar, not counting secondary operations, 213,299 vaccinations were performed, a reduction of 6,387 as compared with the previous year. Primary operations numbered 202,317, and re-vaccinations 10,989, with percentages of success, respectively, of 94·90 and 67·22, as compared with 94·13 and 69·50 in 1896–97. The number of infants protected was 161,278, or 236 fewer than in the preceding year.

Burma.—In 1897–98 the vaccination statistics of Upper Burma have been merged with those of the older province. The Department is administered by the Sanitary Commissioner with the assistance of the Civil Surgeons in their several districts and eleven Native Inspectors. In Rangoon Town the municipal vaccination establishment is under the immediate superintendance of the Municipal Health Officer. The average number of vaccinators employed was 167, as compared with 161 in 1896-97, and the total number of operations performed by them rose from 414,845 in that year to 421,786. Primary operations numbered 400,318, or 9,652 more than in the previous year, but the number of re-vaccinations was only 21,468, or 2,711 fewer. The increase in the number of primary operations, moreover, was not general, and there was a decrease in no less than ten districts, conspicuously in Rangoon, Pakokku, Thaton, Yamethin and Meiktila.

The interdiction of the compulsory vaccination of unprotected adults is to some extent, at any rate, responsible for the grave falling off in the number of vaccinations performed in Rangoon Town in recent years ; but as the Local Government is now taking steps to legalize (1) the vaccination of unprotected persons on board any ship on which small-pox has occurred, (2) the vaccination of unprotected inmates of cooly barracks and lodging houses, and also (3) the serving of notices requiring any unprotected person to be vaccinated within seven days, it may be hoped that the number of operations will increase again.

The ratios of success obtained were, in primary cases 94·56 per cent., and in re-vaccinations 61·38, as compared with 92·43 and 59·50, respectively, in 1896–97 ; the rise being ascribed to improvement in the quality of the lymph supplied from the depôts at Rangoon and Taunggyi.

There was a considerable increase in the number of operations performed by Civil Surgeons and medical subordinates attached to dispensaries, but more than half the total, which was 9,764, against 8,403 in the previous year, were performed in the three districts of Hanthawaddy, Thongwa and Sagaing. Primary operations numbered 5,151 and re-vaccinations 4,613, and 94·95 per cent. and 52·18, respectively, succeeded.

Of the estimated number of children born during the year 111,931, or 34·34 per cent., were protected, against 32·29 per cent. in the preceding year, 22·05 per cent. in 1895–96 and 15·79 per cent. in the three years 1892–93 to 1894–95.

No improvement seems to have been effected in the vaccination arrangements in the Shan States. Although there was some increase in the number of operations performed in the Northern Shan States, the proportion of success continued low and the check was insufficient. In the Southern Shan States there was a falling off in the numbers as compared with the previous year, attributed to the epidemic prevalence of cholera from May to September, in consequence of which the vaccinators were employed in looking after the sick and distributing medicines, while parents, in terror of the disease, would not allow the vaccination of their children.

Improvement is observable in the proportion of cases inspected. The percentage verified by Civil Surgeons was 12·58 and by Native Inspectors 16·52.

Lymph paste was prepared in the depôts at Rangoon and Taunggyi, whence most of the lymph used, which was generally of good quality, was supplied.

Inoculation is still practised in some places, and is said to have led in many cases to outbreaks of small-pox.

Ajmere-Merwara.—Vaccination in this small province is supervised by the Civil Surgeon of Ajmere, assisted by a Native Superintendent. The average number of Vaccinators employed in 1897–98 was 13, and the total number of operations performed

was 16,555, or 273 more than in the previous year. Nearly all were primary operations, which proved successful at the rate of 98·74 per cent.; of the 75 re-vaccinations, 46, or 61·33 per cent., succeeded.

The number of infants protected was 10,996, or about 50·6 per cent. of an estimated birth-rate of 40 per 1,000, as compared with 51·3 per cent. in 1896–97, 46·3 in 1895–96, and a mean of 40·5 in the three years 1892–93 to 1894–95.

Civil Sanitary Works.

Bengal.—As has been explained in previous reports, the figures regarding expenditure on sanitary improvement in Bengal have, since 1895 when the change was introduced, had reference to the financial year ending the 31st of March. In 1896–97, the number of municipalities in Bengal, excluding Calcutta, was 148, an increase of three as compared with the previous year, but the total income, including opening balances in both years, fell from Rs. 46,02,679 in 1895–96 to Rs. 43,49,548; this falling off was, however, almost entirely due to diminished borrowing from Government for capital expenditure. Of the total income about 46·76 per cent. was devoted to original and recurring sanitary works, 10·03 per cent. to roads, 4·49 per cent. to preservation of the public safety, and 28·61 per cent. to other requirements. The expenditure on water-supplies was Rs. 5,44,984, as compared with Rs. 9,96,441 in 1895–96, the large decrease being due to diminished capital outlay. On drainage, expenditure fell, for the same reason, from Rs. 1,49,559 to Rs. 1,21,060. On conservancy, there was an increase in expenditure from Rs. 8,88,026 to Rs. 9,21,519, due to the purchase of land for trenching purposes, and to the adoption of special measures for cleansing towns as a precaution against the invasion of plague.

The average proportion of municipal income expended on original sanitary works was only 3·70 per cent., against 5·03 per cent. in 1895–96. The reduction was general, for in 1895–96 upwards of 10 per cent. of their income was thus expended in seventeen towns, and in 1896–97 in only fifteen, including Meherpur (34·75 per cent.), Netrakona (32·43) and Patuakhali (26·16); while the number of municipalities, in which nothing whatever was so spent, rose from 28 to 37, and included such important places as Hooghly, Berhampur, Bettiah and Ranigunj.

The average proportionate expenditure on recurring sanitary works, however, rose from 37·64 to 40·20 per cent. of income, ranging from 65·14 per cent. in Jangipur, in the Murshidabad district, to 13·14 in Santipur in Nadia, and 8·92 in Netrakona in Mymensingh.

The expenditure of public funds on rural sanitation increased considerably, from Rs. 1,42,012 in 1895–96 to Rs. 4,00,272; and there was a still more remarkable and very gratifying increase in the amount provided by private benevolence, which rose from Rs. 4,94,131 to Rs. 11,72,068. Of this sum, Rs. 1,57,770 was spent on the construction of seven *bunds* in Darbhanga, and the greater part of the remainder was devoted to the excavation of tanks, works which not only furnished work for labourers in a year of famine, but will tend to the permanent improvement of the supply of water in the province.

The only large project completed during the year was the extension of the Bhagalpur water-works, at a cost of Rs. 2,70,955.

The constitution of the Board, and the duties assigned to it, remained unchanged. Owing to the absence of members from head-quarters there was the usual difficulty in arranging for meetings, and only two were held during the year; but in order to prevent the delay of business, papers were circulated among the members.

The following were the principal subjects of discussion at the two meetings of the Board:—

(1) The drainage and sewerage of Calcutta and the South Added Area.

(2) The drainage and sewerage scheme for Howrah; the Board considered that the sewerage scheme should be completed before the drainage works were commenced.

(3) The unfiltered water-supply of Calcutta and the South Added Area; the Board did not receive the complete papers until the work was considerably

advanced, and simply recorded their approval of the work, as, at the stage reached, no advantage could result from criticism of the plans and estimates.

(4) Bhagalpur water-works.

(5) Berhampur water-works.

(6) Darjeeling water-supply.

(7) The septic tank system of sewage disposal. The Sanitary Commissioner suggested that the Board should recommend Government to join with the Calcutta Corporation in making an experimental tank and filter; he was asked to submit an official communication on the subject for the consideration of the Board.

The principal estimates prepared were the following :—

(1) A water-supply scheme for the Garden Reach Municipality, to cost Rs. 50,000.

(2) Remodelling the Darjeeling water-supply scheme, at a cost of Rs. 1,10,000.

(3) A scheme for flushing the road-side drains of the Patna Municipality, to cost Rs. 56,000. The municipality being unable to afford such a large sum, a partial scheme was prepared to provide for the most offensive drains, but the Municipal Committee were enjoined to make every effort to provide funds for the whole scheme.

Estimates and plans were considered for :—

(1) The extension of the unfiltered water-supply in the town and suburbs of Calcutta.

(2) The supply of filtered water to Pabna.

(3) The construction of two tanks in Khulna.

(4) A drainage scheme for Baranagar and South Dum-Dum.

(5) The Cossipore and Chitpur drainage project.

(6) The drainage of Dainhat.

(7) The drainage and sewerage of Howrah.

An interesting experiment was carried out at Patna under the superintendence of the Board's Engineer. The Municipal Commissioners were desirous of ascertaining whether it would be possible to obtain water from the old bed of the River Sone, and so avoid resorting to the Ganges for a supply. A series of borings were made to the west of Bankipore, which showed that a great thickness of river sand was to be found at a few feet from the surface, and that water was standing from 10 to 12 feet below ground level. A masonry well was sunk from which water was continuously pumped for ten hours daily for more than a month. The results showed that an ample supply of pure water could be obtained, and the municipality were requested to supply a map of the town and certain information to enable the Board to prepare an estimate.

In connection with the biological treatment of sewage, a coke-breeze filter for urine and sullage water, which had been working at Dacca during the previous year, proved so satisfactory, that a circular was issued bringing the method to the notice of all municipalities and local officers. It is hoped that the matter will receive the attention that its importance deserves.

The Board furnished advice on a number of miscellaneous questions submitted to them by Government and various local bodies, and their Sanitary Engineer made numerous valuable inspections.

Assam.—The total income of the municipalities, towns, stations and unions in Assam in 1897 was Rs. 2,58,169, as compared with Rs. 2,62,416 in the previous year. The amount spent on sanitary works proper was Rs.1,13,543, or 43·98 per cent. of income, against 46·10 per cent. in 1896. The highest percentage of income set aside for sanitation was 73·89 in Gauhati, the lowest, 21·69 in Sylhet. No important sanitary work was put in hand during the year on account of lack of funds, but efforts were made to improve existing sources of water-supply and arrangements for conservancy. The protected water-supplies at Gauhati and Shillong suffered considerable damage during the earthquake, but they were speedily put in order again, although the pumping machinery at Gauhati is old and worn-out and will soon require to be renewed. In rural areas the principal improvements

consisted in the excavation of tanks and the repair of wells ; a few small drainage works were also undertaken. It is satisfactory to learn that Local Boards, generally, are alive to the importance of such matters and are willing, when they can, to spend money on them.

The Chief Commissioner had under consideration a draft Village Sanitary Regulation, prepared by the Sanitary Board on the lines of the North-Western Provinces and Oudh Sanitary Act II of 1895 ; but rejected it on the ground that no Regulation of the kind is suitable to the sparsely populated hills and jungles of Assam.

No meeting of the Sanitary Board was held, but the opinions of members on all important sanitary matters under discussion were obtained unofficially.

North-Western Provinces and Oudh.—The income of the 103 municipal towns in these provinces during the financial year 1896–97, excluding opening balances, was Rs. 41,52,909, nearly eleven and a half lakhs less than in the previous year ; and the expenditure on sanitary works fell from Rs. 24,63,595 to Rs. 21,79,902. There was a reduction in the expenditure under all main heads, except conservancy. On water-supply Rs. 8,90,523 were spent, as compared with Rs. 10,97,305 ; on drainage Rs. 3,15,108, against Rs. 4,30,079 ; on markets and slaughter-houses Rs. 35,843 against Rs. 47,723 ; on conservancy the sum advanced from Rs. 8,88,488 to Rs. 9,38,428.

No new work of any magnitude was begun during the year, nor was any completed, except the extension of the Allahabad water-supply to Daraganj ; and the following notes refer to the progress of existing works during the year ending 31st March 1898. At Agra, the daily average consumption of filtered water fell from 1,520,115 to 1,338,177 gallons, equal to 7·89 gallons per head per diem of the census population ; in the cantonment the daily average consumption of filtered water rose from 164,702 gallons to 185,718. The maximum consumption in the city and cantonment on any one day was 2,325,991 gallons. The engines and filters are designed to meet a maximum daily demand of only 1,500,000 gallons, and although, by working extra time, the engines can pump up a larger quantity, the area of the filters is too small to allow its being sufficiently slowly filtered. There is a peculiar danger attending over-rapid filtration at Agra, for the stream of the Jumna is very small during the hot weather and the water is liable to be very impure. The urgent necessity for the provision of an additional filter has been pointed out to the Municipal Board, but want of funds is in the way.

The actual cost of the filtered water was 1·80 anna per 1,000 gallons ; but, calculated on the net expenditure, including interest and sinking-fund charges, the cost was 3·43 annas.

At Allahabad, notwithstanding the extension of the municipal mains to Daraganj, which derived its supply of water from the city water-works from October 1897, the consumption of filtered water fell from an average of 1,600,288 gallons a day to 1,425,164, between 8 and 9 gallons a head of the population. The falling off was due in part to the higher rates charged for water for use in gardens, in part to shortened hours of supply in the beginning of the year, but chiefly, it is satisfactory to note, to the prevention of waste.

At Benares, the daily consumption of water rose from an average of 1,768,394 gallons in 1896–97 to 1,905,216, equal to 9·05 gallons per head of the population. Each thousand gallons cost 1·34 anna, not reckoning interest and sinking fund payments ; if these are taken into account, the cost was 2·27 annas. The principal work in progress during the year was the construction of a raised reservoir for maintaining a constant supply. This reservoir is estimated to cost Rs. 79,362, and should have been finished in July 1897, but, owing to delay on the part of the contractors, it was not expected to be ready before the end of July 1898.

At Cawnpore, the daily consumption of water increased slightly from 1,306,426 to 1,325,409 gallons, or 8·09 gallons per head. The receipts are still low as compared with other towns and the cost of the water is consequently high.

At Dehra Dun, the average daily supply was equal to 6 gallons per head. The supply was scanty during part of the hot weather, not due to failure of the spring, but to lack of supervision.

At Lucknow, the total quantity of water pumped into the mains was 346,581,925 gallons, of which 63,058,814 gallons were supplied to the cantonment. The average daily consumption in the city was 776,776 gallons, equal to 4·8 gallons a head, as compared with 2·95 in the previous year.

At Meerut, the average daily supply was 461,899 gallons, compared with 350,508 in 1896–97, or 6·3 gallons per head of the census population, against 4·55 in the previous year. The cost of delivery, excluding sinking-fund and interest charges, was 1·7 anna

per 1,000 gallons, and it is expected, when the supply is extended to the cantonment, that this will not exceed one anna.

At Mussoorie, the daily average supply was equal to about 7 gallons a head.

At Naini Tal, the total quantity of water pumped was 6,192,830 gallons, costing about 17 annas a head of the population. Several improvements to the existing works were made during the year, and a detailed project of reconstruction and extension was prepared.

The water supplied to the towns generally during the year is reported to have been good, but at Agra, Allahabad and Lucknow microbes, resembling that associated with the causation of enteric fever, were detected in the supply, and measures to remedy defects, which may have led to their presence, were in each case undertaken.

Progress was made with the Benares sewage project, mainly in the construction of branch sewers in the unsewered area. The Bhilaru sewage shoot at Mussoorie was in course of construction, but work was unfortunately delayed by severe weather in the winter. The town of Jhansi was surveyed and a scheme for a supply of water to be pumped from wells was prepared. Surveys for the surface drainage of Deoband, Aligarh, Saharanpur and Fyzabad were in progress or completed.

The members of the Sanitary Board met twice during the year, and the following were the more important matters discussed by them :—

1. Posting of Assistant Surgeons to districts as "Sanitary Assistants." The proposal was to post the Assistant Surgeons to ten selected districts, but it was resolved to recommend to Government that one Assistant Surgeon should be appointed for all three hill districts ; that an Assistant Surgeon should be posted to Basti, and another to Azamgarh on account of the density of the population of these districts and the frequency in them of epidemic diseases, and that an Assistant Surgeon should be posted to each of the other seven districts specified by the Inspector-General of Hospitals—a distribution of the ten Assistant Surgeons to twelve districts.

It was further resolved,

(*a*) that in the remaining thirty-six districts, Hospital Assistants, selected on account of their knowledge of sanitation, should be appointed ;

(*b*) that Assistant Superintendents of Vaccination could not be dispensed with if the registration of vaccine operations was to continue true and accurate, and that such posts should be given to selected vaccinators ; and,

(*c*) that a lectureship on Hygiene should be established at the Agra Medical School.

2. A memorandum, prepared by the Sanitary Commissioner on the subject of the disposal of night-soil in municipalities, was circulated for the guidance of Municipal Boards.

3. The high rate of mortality in the town of Deoband was attributed to inefficient drainage, due to the want of a proper outfall under the North-Western Railway, and the railway authorities were addressed with a view to measures being taken to improve the outfall before the next rainy season.

4. The question of employing a mechanical engineer for the supervision of the pumping machinery of the various water-works was referred to the Municipal Boards concerned, to ascertain whether they would contribute towards his pay.

5. It was recommended to Government that, in view of the increase in the statistical work in Civil Surgeons' offices, each Civil Surgeon should be allowed an additional clerk.

Punjab.—The total income of the 31 municipal towns in the Punjab in 1897, including an opening balance of Rs. 10,92,066, was Rs. 52,95,950, a falling off due to a smaller opening balance of about a lakh as compared with the previous year. Of the total, Rs. 2,17,183 were expended on water-supply, against Rs. 1,66,744 in the previous year ; Rs. 1,02,847 on drainage and sewerage, against Rs. 1,26,608 ; and Rs. 6,35,308 on conservancy, against Rs. 5,83,174 ; the total sanitary charges aggregating Rs. 11,67,891, as compared with Rs. 12,36,690 in 1896.

The amount realised from the sale of manure and street sweepings was Rs. 1,49,120, an increase of upwards of Rs. 13,000 as compared with the previous year.

No new sanitary undertaking of any magnitude appears to have been begun during the year, but the Pind Dadan Khan water-supply scheme was completed; two storage tanks in connection with the Bhiwani water-supply project were excavated; and the water-supply of Kohat was extended to the cavalry lines, to the *katcheri* and to the charitable dispensary. Improvements to the Peshawar supply were effected; experimental borings in connection with the Amritsar water-supply scheme, now ready for submission to Government, were made; estimates for the Delhi water-supply extension scheme were submitted to the Local Government; experiments were made in connection with a scheme for Mooltan; and a project to supply the cantonment of Mian Mir was being prepared.

A sum of Rs. 78,214 was spent on the Lahore sewage and drainage scheme; and a tramway project for the improvement of the scavenging of Lahore was being prepared for the approval of the Sanitary Board. A large egg-shaped intercepting sewer was constructed in Jhelum; and a number of drains were constructed in Peshawar City, at a cost of Rs. 10,633. Drainage schemes for Mooltan, Rawalpindi, Hazro, Delhi (Chandni Chauk), Balabgarh, Jagraon, Raikot, Fazilka, Muktsar and Batala were under preparation, and schemes for the drainage of Ferozepore City and Cantonment, and of Ladwa were under consideration.

The sewage farm, in the neighbourhood of Delhi, was so far a success that all the filth of the city was disposed of without causing any nuisance.

One hundred copies of the village sanitary inspection books were supplied to Deputy-Commissioners. These books have been kept up in many villages and "have proved "useful in giving important sanitary information to the inspecting officers at the time of "their visit to the villages."

Only one meeting of the Board was held during the year. The following subjects were discussed:—

1. The excessive mortality from fevers in the province.
2. The unhealthiness of the villages in the Neli Circle tract in the Kalsia State and British Territory. It was recommended that quinine should be distributed gratuitously to the villagers all the year round.

A good many papers, of which the greater number related to sanitation in Bengal and the North-Western Provinces and Oudh, were circulated among the members of the Board.

Central Provinces.—The total income of the nineteen *Sadar* towns in the Central Provinces fell from Rs. 16,26,680 in 1896 to Rs. 14,10,350, but the expenditure on sanitation rose from Rs. 2,79,252 to Rs. 2,88,047, the outlay on water-supply being Rs. 61,437, against Rs. 52,420 in 1896; on conservancy Rs. 2,03,702, against Rs. 2,05,089; on buildings Rs. 4,887, against Rs. 16,895. No project of capital importance was undertaken during the year, but progress was made with the water-supply and drainage schemes at Jubbulpore, and with the Wardha water-works which have since been completed. The carrying out of the water-supply scheme at Harda had to be deferred owing to lack of funds.

Of Rs. 94,566, allotted during the year for expenditure on village sanitation, only Rs. 38,845 were spent, about two-thirds on water-supplies, and the balance on site-cleansing, drainage and roads. Progress was made in the record of notes on village sanitation, but the inspection of minor villages was restricted on account of the special duties in connection with the famine and precautionary measures against plague, which engaged the attention of the sanitary staff.

The constitution of the Board remained unaltered; the members met once at each divisional head-quarters, and were mainly occupied with minor projects for the improvement of villages.

Berar.—The income of the municipal towns in Berar was Rs. 2,67,286 as compared with Rs. 2,42,922 in 1896. The proportion devoted to sanitation was somewhat less in 1897 than 1896—71 per cent., as compared with 74, but the actual sum expended was Rs. 1,69,159, only Rs. 1,356 less. The decrease in expenditure was under the heading "water-supply," Rs. 57,904 having been spent, against Rs. 71,180 in the previous year; under the other heads expenditure was larger, on conservancy Rs. 66,853, against Rs. 59,988; on drainage Rs. 10,592, against Rs. 10,208, and on other sanitary works Rs. 33,810, against Rs. 29,139.

No new work of importance was begun during the year, and the principal item of expenditure was a sum of about Rs. 25,000 for repairs to the Khamgaon tank, undertaken as a relief work. Considerable improvements were made in the drainage arrangements of the towns, and a scheme for the drainage of Amraoti, prepared by Dr. Khote, chairman of the sub-committee for sanitation in that municipality, is under consideration.

Night-soil is trenched and cropped in most towns, but owing to the want of rain in 1897 the crops obtained were unsatisfactory, except at Shegaon where there was a fair yield of tobacco. Sufficient attention has not as yet been given by all the committees to the disposal of night-soil, and the filth will be got rid of more effectively and the profits to the towns will be greater when the needed improvements are brought about.

The income of the District Boards is said to be about six-and-half lakhs. In 1897, Rs. 1,05,475 was devoted to sanitation, against Rs. 82,695 in the previous year. The principal expenditure was Rs. 55,939 on water-supplies, against Rs. 28,950 in 1896, and Rs. 38,650 on conservancy as compared with Rs. 37,217.

The District Sanitary Boards met at each district head-quarters during the year, but no details regarding their proceedings have been furnished.

Madras.—Excluding the Presidency Town, the estimated income of the 58 municipalities in Madras in 1897 was Rs. 32,28,120, or about a lakh less than in the previous year. In spite of the diminution in their resources there was a very large increase in the sanitary allotment, which rose from 48·1 per cent. of the income to 63·6 per cent. ; the actual sum being Rs. 20,52,273, about four-and-a-half lakhs in excess of the allotment in 1896.

The actual expenditure, during the nine months ending on the 31st December 1897, was Rs. 11,37.397, including Rs. 4,07,095 on water-supply, Rs. 4,63,861 on conservancy, and Rs. 1,63,353 on the improvement of sites. The total expenditure was more than half the allotment, and the Sanitary Commissioner considers this satisfactory.

The municipal income of the Presidency Town was Rs. 14,42,070, and a sum of Rs. 19,04,424 was allotted to sanitation. This large sum, however, includes the money to be spent on water-supply and drainage works ; and the actual expenditure during the nine months was Rs. 4,55,332, including Rs. 2,38,068 on conservancy.

The Sanitary Engineer furnishes a concise table showing exactly the work which has been accomplished and what remains to be done in the fifty-eight municipal towns. In nine towns water-supply schemes have been completed, against three into which drainage projects have been introduced. Three water-supply schemes are in progress, five are in abeyance, seven are under consideration, and 12 surveys have been made but schemes have not yet been prepared. Four drainage schemes are in abeyance and two are being considered. Twenty-two towns have not been surveyed for the preparation of water-supply schemes, and 33 remain to be surveyed for drainage.

The water-supply works at Conjeeveram were completed in July 1897, and those at Kurnool in the following October. The work at Conjeeveram was less costly than had been anticipated, and it is proposed to devote the savings to fencing-in the pumping station, the construction of a service reservoir, and the extension of pipe-lines in the town.

The new works at Kurnool are designed to supply 15 gallons per head *per diem* to a population of 30,000. The water is pumped from the Kurnool-Cuddapah canal to a storage reservoir, sufficiently highly placed to command the town. From the storage reservoir the water passes to four filters together capable of filtering 450,000 gallons in the 24 hours, and from the filters to a clear-water reservoir, whence it is distributed to the town in iron pipes. To avoid interruption in the supply, a second pumping engine is in reserve, and the storage reservoir is capable of holding fifteen days' supply, so that the canal can be closed annually for repairs. In the town there are 46 public fountains and 13 hydrants.

The total income of the district boards was Rs. 79,10,730, about Rs. 57,000 less than in 1896, and the allotment for sanitary purposes was 8·4 per cent. of the income in both years. During the nine months of the financial year, 58·3 per cent. of the allotment was actually spent, including Rs. 2,48,065 on conservancy.

The Sanitary Commissioner points out the difficulty that must exist in dealing with epidemics in rural areas in the absence of any one capable of directing the measures that ought to be taken ; but a draft bill, which, it may be hoped, will strengthen the hands of

local authorities and enable them to appoint a sufficient staff to secure sanitary conditions by legal measures, has been circulated to those concerned for criticism.

Although alterations in the *personnel* took place during the year, the Board continued to work under the constitution framed by the Local Government in 1896. The Board was consulted by Government regarding rules regulating the formation of towns in the vicinity of railway stations and formulated a set of rules which might be usefully applied in, or modified to suit, other provinces. The Board scrutinised the plans and estimates for 185 sanitary projects, aggregating in value nearly twelve lakhs of rupees, of which 54 were for municipalities and 131 for local fund boards.

Coorg.—Besides the construction of drains in Somvarpet and a preliminary survey of Virajendrapet, no sanitary work appears to have been completed in any of the small towns in Coorg.

The Board met three times during the year, and among other matters discussed the following :—

(1) The heavy mortality among coolies going to and from the province. The cooly shelters, three of which have been opened and have proved most useful, have not served to check heavy mortality, and, although it was pointed out that many of the poor who died were beggars and were not looking for work, the Civil Surgeon considered that a simple labour law, providing for the licensing of labour contractors, the medical examination of coolies, the unfit being returned to their homes, and the treatment in hospital of those who become sick, was required. After discussion, however, the matter was allowed to drop.

(2) Measures to be taken against the invasion of plague. A series of simple rules drawn up by the Civil Surgeon were distributed for the guidance of the public.

(3) The excessive mortality in April, May, June and July. This was ascribed to malarial fevers, and a set of simple rules dealing with the personal prophylaxis and treatment of such fevers was circulated among the people.

Bombay.—Excluding Bombay City, the total income of the 167 municipalities in the Presidency in 1896-97 was Rs. 58,92,572, against Rs. 55,22,074 in the previous year. The sanitary allotment was 57·21 per cent. of the total income, or Rs. 33,71,008, and 84·84 per cent. of this sum was actually spent, as follows :—Rs. 9,07,896 on water-supply, against Rs. 6,47,329 in the previous year ; Rs. 14,77,597 on conservancy, against Rs. 11,06,662 ; and Rs. 1,71,085 on improvement of sites, against Rs. 2,22,905. Owing to the famine and the presence of plague but little progress was made on large schemes of sanitary improvement, but the towns received such a thorough cleansing that their condition is probable purer than it has been at any previous period of their history. If this improvement is maintained, much will be gained even if, as is to be feared, some of the larger schemes are deferred for want of the funds, which have been devoted to precautions against the invasion of plague. It will be gathered, however, from the following short notes on projects of sanitary improvement recently completed, in progress, or in contemplation in some of the towns, that municipal committees can often evade the prosecution of schemes of sanitation without pleading poverty.

Ahmedabad is an exception to the general rule, on account of the foresight and energy of the Honourable Mr. Runchorlal Chotalal, whom the townspeople are fortunate in having as the president of the municipal committee. This gentleman has been able to force through the committee schemes for water-supply and drainage. The water is, as usual, thoroughly appreciated by the people, and the demand has become so great that an extra pumping engine has been ordered.

At Ahmednagar, a scheme for supplying water to about one-third of the town has been completed ; and a project on similar lines for the supply of the rest of the town has been drawn up, but its execution depends on the construction of the Kapurwadi tank which, undertaken as a famine work, has only been one-fourth complete.

At Dhulia, the water-supply project was completed.

At Shikarpur, the municipality have shelved a small scheme for water-supply, preferring to rely on wells ; and every year new ones are sunk in the sewage-sodden subsoil, mostly in the floors of the houses, or in the small enclosures where cattle are kept.

At Sukkur, there is now a fairly good supply of water derived from tunnels driven in the rocky bed of the Indus. The water is pumped by a pair of engines to iron tanks

on a small hill, and is thence distributed by iron pipes to cisterns and stand-posts in the town.

At Surat, the water-works are nearly finished. The water is pumped from covered wells, sunk in the bed of the river Tapti, to steel tanks raised on towers, whence it is supplied to the city by gravitation. It is noted that, although the influence of the tide affects the level of the river much higher up than the head-works, the quality of the water is not affected.

At Yeola, the water-works, which were being carried out by the Public Works Department, were at a standstill on account of the non-arrival of pipes and engines ordered from England a year before.

At Ahmedabad, a drainage scheme, drawn up by Mr. Baldwin Latham, has been applied to a section of about one-fifth of the city, and has proved so satisfactory that it is about to be extended to the rest of the city. The sewage farm continues to be badly managed, but the municipal committee have acquired 300 acres of land about three miles away from the town, where it is hoped that sewage farming, as carried on at Karachi, will prove a success.

Karachi is another town in which the *personnel* of the committee and executive has secured progress in sanitation. The drainage scheme on the Shone system has been completed, and, the difficulties encountered on account of the height of the subsoil water having been overcome, is entirely satisfactory ; house connections are being rapidly made, and it only remains to extend the system to the cantonment. The sewage is utilized without nuisance and profitably, on a broad-irrigation farm. The amount of water brought into the town of Karachi has rendered it unhealthy, but it is hoped at once to diminish this evil, and to check waste by the imposition of a water-rate.

At Poona, where schemes for water-supply and sewerage have been pressed on the committee for years, no permanent improvement has as yet been effected. The Sanitary Board advised some check being placed on the waste of water in the *sadar bazar*, where the dampness of the soil, due to the urgent need for drainage, is a cause of sickness.

Sholapur town is at present drained chiefly by open channels, which are such a serious nuisance that the committee have been convinced of the necessity to substitute pipe sewers, and a scheme has been prepared by the Public Works Department.

At Sukkur, a specially appointed engineer has drawn up an excellent and economical scheme of drainage for the municipality, but the committee are hesitating between it and an extension of their present drains, which are described as elongated cess-pools.

The income of the various district funds rose from Rs. 40,05,823 in 1895-96 to Rs. 41,45,747 ; the sanitary allotment from Rs. 6,85,851 to Rs. 8,64,063, and the actual expenditure from Rs. 4,71,536 to Rs. 5,16,221.

The Bombay Village Sanitation Act was introduced into 62 villages during the year, raising the total in which it is in force to 282.

The constitution of the Board remained unchanged. The number of meetings is not stated, but much useful work was done in connection with the projects above referred to, and with schemes for the water-supply, drainage or improvement of the towns of Godhra, Dakor, Malegaon, Gadag, Tirkhundi, Khed, &c.

The Board reiterate their opinion that the cause of sanitation will be furthered by the judicious reward of the few influential men who use their position to overcome the opposition of their fellows to schemes of sanitary improvement.

Burma.—The aggregate income of the towns and districts in Upper and Lower Burma fell from Rs. 71,10,986 in 1896 to Rs. 64,91,740, and the proportion of the total set aside for sanitary purposes fell from nearly 35 to a little over 33 per cent. The actual expenditure was Rs. 21,50,918, distributed as follows :—On water-supply Rs. 2,41,137; on drainage Rs. 1,19,799 ; on conservancy Rs. 8,12,295 ; and on other sanitary works Rs. 9,77,687. As compared with 1896, there was a total decrease in expenditure of about three lakhs of rupees, mainly attributable to reduction of the sums spent on water-supply, for a decrease of two lakhs and forty thousand rupees under the heading " Drainage " was almost balanced by an increase of two lakhs and thirty-eight thousand spent on conservancy, and the sums spent on other sanitary works were approximately equal in the two years. As Colonel Sinclair remarks, " Considering the urgent need of sanitary reforms in the " majority of the towns, the amount spent on water-supply, drainage and conservancy is " very inadequate."

No new scheme was undertaken during the year, and very little practical action

in improving existing projects. In Rangoon the question of improving the water-supply is becoming yearly more urgent ; not only is the quantity certain to be seriously deficient in a year of scanty rainfall, but the catchment areas of the Victoria and Royal Lakes are subject to dangerous pollution. The Thamaing water extension scheme, which provides for a reservoir of a storage capacity of 5,827 million gallons, has been prepared, and is estimated to cost Rs. 20,00,000 ; this, with the existing supply from the Victoria Lake, it is hoped, would suffice for the wants of Rangoon for nearly sixty years to come. This project has been postponed pending a consideration of a scheme to obtain supplies from artesian wells, but the municipal committee, after a careful examination of the matter, have definitely decided that artesian wells are not suitable as a source of public water-supply in Rangoon. After the success which attended their somewhat adventurous embarkation on a sewerage scheme, it is astonishing that the municipality cannot come to some decision regarding the provision of a water-supply.

The Shone system of sewage disposal worked admirably without a hitch, and satisfaction with the working is growing from year to year. During the year 861,091,00 gallons of sewage were disposed of at a cost of little more than one anna-and-a-half per 1,000 gallons.

An interesting experiment in street-paving was made in the substitution of wood-paving for stone metal in a portion of one of the busiest streets in the town. The wood-paving has, so far, been entirely satisfactory, and a further stretch has been laid down.

At Moulmein, money was set aside for plans and estimates for a water-supply scheme, but no progress has been made pending the result of some well-boring experiments which, it is believed, will materially lessen the cost of the project.

At Bassein, also, tube-wells are being considered as a source of water-supply.

At Mandalay, the supply of water is still obtained from wells, from the moat, and from the Irrawaddy. The scheme to obtain a public supply from the river has been abandoned owing to engineering difficulties. A night-conservancy project has meanwhile ousted schemes of water-supply from the attention of the municipal committee, and a loan of 4½ lakhs was provided by Government for conservancy works ; but, at the last moment, the committee have fallen into doubt regarding the efficiency of their conservancy scheme, and have decided to apply it on a small scale in a few blocks of the town before committing themselves to heavy expenditure.

At Prome, a new filtration scheme is under consideration of the committee ; the unfiltered water, as now supplied, has been pronounced bad and unfit for use.

The village sanitary rules, issued in 1895, are reported to have worked well, and to have led in many cases to improvements in drainage and conservancy. In December 1897, a permanent sanitary record was introduced for use in towns and villages, which, it is hoped, will still further stimulate interest in rural sanitation.

The number of meetings of the Sanitary Board is not stated, and the Board were still occupied with the scrutiny of preliminary survey maps prepared for municipal towns. A sanitary engineer was appointed in January 1898 ; but the Sanitary Board's relation to him seems to be limited to the privilege of consulting him.

General Remarks.

International Conference at Venice.—The Government of India were represented at the International Conference, that sat at Venice from the 16th of February to the 19th March 1897, by their Sanitary Commissioner, then Surgeon-Major-General James Cleghorn, and by Surgeon-Colonel Richardson, who had recently retired from the office of Inspector-General of Civil Hospitals in the North-Western Provinces and Oudh.

The result of the deliberations of the Conference was the promulgation of the International Sanitary Convention of Venice of 1897, a series of regulations designed to prevent the spread of plague with the least amount of inconvenience to the public and to commerce, which in the opinion of the delegates was compatible with safety.

The Red Sea Pilgrim Traffic.—The Haj of 1897 began upon the 11th of May, but the assembly of pilgrims was much smaller than usual, the total number being only about

two-thirds that of the previous year. Several causes contributed to this result. In the first place, the Haj of 1896 was a Haj-i-Akbar, and it is the rule for the succeeding pilgrimage to be a small one. The Græco-Turkish war, it is stated, had the effect of preventing pilgrims leaving the belligerent countries. But the chief reason was the presence of plague in India, and the alarm experienced in consequence by European Governments, lest the Hejaz should be infected and become a centre of dissemination by returning pilgrims. It was feared in India that, unless steps were taken to allay the alarm in European countries, stringent measures would be directed against arrivals from India ; and, in spite of their reluctance to issue any orders which would interfere in any way with the religious observances of the people, the Government of India prohibited the departure after the 1st February from Bombay and Karachi of pilgrim ships. At the same time every effort was made to explain to the public the situation of affairs, so that intending pilgrims might be persuaded to defer their pilgrimage. As Calcutta and Madras were free from plague, it was made known that pilgrims might start from these ports, and the local authorities were warned to be prepared for an influx of pilgrims.

There was, of course, a danger lest pilgrims who had already assembled in Bombay might carry the plague with them to Calcutta and Madras, and to guard against this, instructions were given to dissuade pilgrims, who had already arrived in Bombay for the purpose of embarking, from seeking another port. Arrangements were made for the preliminary detention in segregation in Bombay of those who insisted upon going to Calcutta or Madras, and it was suggested to the authorities at Calcutta and Madras that they should detain such intending pilgrims, under strict medical supervision, in camps at a distance from the ports.

But the authorities in Madras and Bengal and many public bodies in those provinces did not think that these precautions were adequate, so that on the 16th of February the Government of India issued a notification under the Epidemic Diseases Act forbidding all persons resident in Bombay or Sind, including those who had entered these provinces on their way to the Hejaz, embarking at any port in British India for the purpose of proceeding to the Hejaz.

On the 20th of February, in consequence of a communication from Her Majesty's Secretary of State, a further notification was issued, suspending the pilgrimage from India for that season. Intending pilgrims, after suitable precautions had been taken, were sent to their homes at the expense of Government. About one hundred and fifty Central Asian pilgrims begged to be allowed to remain in India until the next season, and this was allowed. Such of the indigent as wished to go back to their homes in Central Asia were furnished with funds for the purpose and certificates showing the dates on which they had left infected places.

But directly one Haj ends another begins ; and poor pilgrims leave India for the Red Sea littoral in the autumn, before the steamship fares are raised in anticipation of the main body of intending Hajis. Before, therefore, orders restricting and finally forbidding the pilgrimage from India were issued a good number of pilgrims had already left India. Between the 1st of October and the 1st February seven steamers had left Bombay, conveying a total of 4,200 pilgrims. One steamer left Calcutta on the 21st January with 60 pilgrims. No pilgrims sailed from Madras.

Among the pilgrims who left Bombay, there were in all only 13 deaths on the voyage to Camaran, but two of the deaths were due to plague. These two deaths occurred on the S.S. *Pekin*, which left Bombay on the 28th December 1896 with 1,045 pilgrims on board. No other case occurred among the *Pekin's* passengers, or among the passengers of any other steamer, either on the voyage or at the quarantine station at Camaran.

The Quarantine Station at Camaran.—The quarantine station at Camaran was opened for the season for the reception of pilgrims on the 6th December 1896. Thirty vessels arrived during the season and brought 14,210 pilgrims, including 2,493 natives of India and 327 Afghans. A quarantine of ten days was, as usual, imposed upon arrivals from Indian ports ; but on the 8th of February orders were received from Constantinople increasing the quarantine for Indian ships in ordinary cases from ten days to fifteen, and fixing a period of twenty days for any vessel on which plague had occurred. There was no case of plague or cholera among the pilgrims at Camaran, and there were only 15 deaths among them altogether.

Improvements in the sanitation of Camaran were being carried out, which, when completed, will promote the health and comfort of the pilgrims detained there. During the season of 1897 condensed water was issued for the first time to the pilgrims, who

expressed their strong approval of the quality of the water. The condenser is capable of producing 80 tons of water a day; pipes are laid down to all the camps; and in 1897 every pilgrim was given ten litres of the water daily free of charge. An ice machine was also in operation, but no ice was issued to the pilgrims. Two disinfecting machines were taken into use.

The Return of the Pilgrims.—Although by the time the pilgrims were due to return plague had for the time greatly abated in Bombay, there was, of course, a great danger in allowing a large number of poor strangers to go into the town. Arrangements were accordingly made to prevent the mixing with the townspeople of the returning pilgrims, by taking them direct from the ship to the railway station and sending them in batches by special trains to their destinations, the local authorities concerned being advised of the despatch of each train. Such of the pilgrims as could not afford to pay for them were given tickets gratis.

On the 10th of June the Consul at Jeddah telegraphed that plague had broken out there. The Government of India then directed the Governments of Bombay and Bengal to enforce the regulations prescribed by the Convention of Venice against arrivals from the Hejaz, and special instructions were given for the disinfection of ships on which cases of plague might have occurred. Happily no case occurred among the returning pilgrims.

Four steamers arrived in Bombay with a total of 2,519 returning pilgrims on board. Only 20 deaths occurred on these vessels during the voyage to Bombay. Two of the steamers arrived at Bombay on the 10th June, and one of these, the *Pekin*, had on board over 400 pilgrims, whose destination was Calcutta. After landing the pilgrims for Bombay, the *Pekin* left for Calcutta, and 443 pilgrims were disembarked at Diamond Harbour. Three deaths occurred among the *Pekin's* pilgrims—one from phthisis and two from chronic diarrhœa, apparently on the voyage from Bombay to Calcutta. Two of the steamers arrived at Bombay after the Hejaz had become infected with plague, and the effects of the pilgrims on these vessels were disinfected prior to the despatch of their owners to their homes.

Anti-plague inoculation.—Extensive trial has been made of the inoculation with different serums for the cure of plague; and the preventive inoculation devised by M. Haffkine has been largely used in very many parts of the country. As, however, it is understood that anti-plague inoculation is one of the principal subjects engaging the attention of the members of the Indian Plague Commission, any criticism of the results hitherto obtained would at present be out of place here. Suffice it to say that, in view of the hopeful results which were obtained in the early experiments, every endeavour has been used by Government, not only to place M. Haffkine's preventive inoculation within the reach of those exposed to the infection of plague, but to encourage such persons to avail themselves of the protection.

Researches by the Special Assistant.—Brigade-Surgeon-Lieutenant-Colonel D. D. Cunningham had to leave India for Europe seriously ill in the end of March. During the first two months of the year he continued his researches into the physiological action of cobra venom, and the results of his work have been published in Part XI. of the Scientific Memoirs of Medical Officers of the Army of India.

The Etiology of Malarial Fever.—Until recently, our conception of the theory of the propagation of malarial fevers by the parasite discovered by Laveran was limited by the fact that no one had been able to discover the organism in external nature; and the difficulties surrounding the subject were so great that this discovery seemed to be almost hopeless. In 1894, however, Dr. Patrick Manson stated in a definite way a theory that the parasites are capable of transference to mosquitoes feeding on the blood of infected persons.* The belief that malarial fever was in some way connected with mosquitoes was not a new one; indeed, it appears that a connection between insects and malarial fever was suspected before the beginning of the Christian era.† In modern times a theory of the conveyance of malarial infection by mosquitoes existed in the United States, but seems to have remained unknown in Europe; and even the suggestion made

† *See* paper by Dr. George H. F. Nuttall, in the Centralblatt für Bakteriologie, Parasitenkunde und Infektionskrankheiten, 14th February 1899, and following numbers.

more than once by Laveran himself,* that possibly mosquitoes played a part in the propagation of paludism as they do in filariasis, did not attract attention. It was not until the publication of Dr. Manson's paper on the subject that the minds of British observers, at any rate, were turned seriously to the mosquito as a possible intermediate host.

In 1895 Surgeon-Major Ronald Ross, of the Indian Medical Service, began the experimental study of the subject in India ; but for more than two years, during which he fed vast numbers of mosquitoes on persons suffering from malarial fever, he failed to obtain any conclusive evidence in favour of Manson's hypothesis.

Meanwhile, however, belief in the connection between malaria and mosquitoes was gaining ground, and it is of interest to quote the remarks of Dr. Robert Koch, who studied the subject in German East Africa :—

"With regard to the method of the origin of tropical malaria, I have arrived at "no certain conclusions. One cannot as yet go beyond conjectures. But the number "of possibilities which may be discussed in this regard are now with increasing knowledge "of the actual nature of malaria, being continuously limited, and there now remain, so far "as tropical malaria is concerned, only two agents for the conveyance of infection which "need be seriously considered. These are drinking-water and mosquitoes. The more I "study this disease, the more I incline to the opinion that the latter is the chief, and "probably the only factor. Wherever one turns, one finds a local and a seasonal "relationship between the existence of tropical malaria and the presence of mosquitoes. "On the coast there are a few places which are regarded as free from malaria ; one of them "is the island of Chole, which lies at the southern extremity of the large island of Mafia. "I have visited this island, which in former times was used as a sanitarium by the Zanzibar "Arabs. It is the only place on the coast where I was able to sleep without mosquito-"curtains. Among mountains malaria stops exactly where there are no longer any "mosquitoes. In the interiors of countries malaria diminishes where mosquitoes "diminish. At the times of the year when mosquitoes abound malarial fevers are most "frequent.

"I am most strengthened in my conviction by the analogy of malaria with Texas "fever and other tropical diseases of men and animals, in which the parasites are found in "the blood exclusively. In all these diseases the infection is carried by blood-sucking "insects, not indeed that the insect carries the infectious matter direct from the blood of "one animal to that of another, but the parasite goes through further developmental stages "in the insect, passes into the eggs and into the young insects, and is by them carried to "the proper host. In this or some similar way I think the mosquito plays its part in "regard to tropical malaria."†

In August 1897, Surgeon-Major Ross's perseverance was at last rewarded. He observed in the stomach of a particular kind of mosquito, fed on the blood of a person suffering from malarial fever, certain pigmented cells. From the resemblance of the pigment in those cells to that found in the organisms associated with malaria, he was led to hope that he had found an extra-corporeal development of the latter.

Major Ross' Discovery.—In February 1898, Surgeon-Major Ross was placed on special duty under the Sanitary Commissioner with the Government of India for the investigation of the malarial problem and *kala-azar*, and was given the use of the laboratory of the Special Assistant to the Sanitary Commissioner in Calcutta.

Surgeon-Major Ross at once resumed the study of the pigmented cells. After some experiments attended by negative results, he found that the pigmented cells were almost always present in a particular variety of mosquito,—a mosquito capable of carrying *filaria nocturna*,—after it had been fed on sparrows infected with *proteosoma* Labbé, which is a parasite nearly akin to the parasites associated with malarial fever in man. After examining a very large number of such mosquitoes fed on infected birds, controlling his experiments by the examination of insects of the same variety fed on healthy birds, Surgeon-Major Ross satisfied himself that the pigmented cells are a developmental stage in the mosquito of the blood parasites of the infected birds. He was, however, able to trace the gradual growth and development of the cells in the insects.

Shortly after the mosquito has been fed on the infected blood, the cells begin to appear,

* Du Paludisme et de son Hématozoaire, Paris, 1891, page 147, and again on page 60 of the Volume on Paludisme in M. Léauté's Encyclopédie Scientifique des Aide-Mémoire, Paris, 1892.

† *Die Malaria in Deutsch-Ostafrica.* Arbeiten a. d. Kaiserlichen Gesundheitsamte, Volume XIV., page 299.

according to Ross, as small oval bodies containing pigment attached to the outer wall of the insect's stomach. These bodies rapidly increase in size, until after six days they reach a maximum of about 60 micromillimetres in diameter, and are protruded freely into the cœlum, or blood cavity, of the mosquito. Major Ross considers these bodies to be coccidia, and calls them *proteosoma* coccidia.

The next object was to discover the sporulation of the *proteosoma* coccidia; and Surgeon-Major Ross soon satisfied himself that there are two kinds of reproductive elements, (*a*) delicate thread-like bodies, and (*b*) large black spores.

And now the enquiry became of particular interest, for there was reason to suppose that the mode of infection of birds with proteosoma certainly, and the mystery of the infection of man with the organism of malaria probably, would be explained by the results of the next step in the investigation.

The results attained were somewhat unexpected, as Ross himself states. He discovered that the thread-like bodies have the faculty of entering and remaining in the large grape-like cells of the salivary gland of the mosquito. This gland lies near the head of the insect, and a duct runs from it to the extremity of the tongue or epipharynx, one of the stylets of the proboscis which is used by the mosquito to pierce the skin of its victim. Ross believes that the secretion of this gland is poured into the wound, its function being to prevent the contraction of the torn capillary vessels, and its effect the familiar irritation of the mosquito bite. His theory of infection was that the thread-like reproductive elements of the *proteosoma* coccidia, having accumulated in the gland, were carried out by its secretion into the blood of any creature on which the mosquito might feed. Once in the blood, *proteosoma* infection would be set up, provided the victim of the mosquito was a susceptible bird.

So far, this theory was supported only by the life-history of the *proteosoma*, and Ross next endeavoured to confirm his speculations by the direct infection of healthy birds. He fed a number of mosquitoes on birds infected with *proteosoma*, and, after keeping them for a week in order to allow time for the production by the *proteosoma* coccidia of the thread-like bodies, he fed the mosquitoes on birds which he had previously ascertained were free from *proteosoma* infection. The result was decisive. After a definite incubation period of from five to eight days, 80 per cent. of these birds became infected with what he describes as immense numbers of *proteosoma*. Most of the birds died and showed the characteristic black pigmentation in the liver and spleen. Major Ross states that *proteosoma* infection is found in only about 13·5 per cent. of the free sparrows which he examined in Calcutta, and then the parasites are far inferior in number to those in his experimental cases. He, therefore, considers that the fact that *proteosoma* infection is carried from a diseased to a healthy bird by mosquitoes has been placed by him beyond question.

Major Ross has not yet succeeded in extending these latter observations to human malaria, nor has he yet ascertained the function of the black spores; and work in both directions must be completed before the problem of the propagation of malarial fever can be said to be solved. He fears, moreover, that the task of finding the appropriate definite hosts for each of the different gymnosporidia will prove to be a hard one. Major Ross is, however, inclined to anticipate that the direct infection of the malarial germs through the suctorial apparatus of the mosquito will be found to be the only method of infection. If this is so, the prevention of malaria will depend upon the prevention of mosquito bites. This may not be so difficult as is supposed, because at any rate as regards several species, mosquitoes have a limited area of propagation, in barrels of water, puddles, and ditches, where small fish, which devour them greedily, cannot live.

Before the important subject of limiting the propagation of mosquitoes is considered, the species and habits of the insects which act as hosts to the parasites must be learned, and this work is now obtaining serious attention in many parts of the world. In the meantime it may be stated that there is good ground for the belief that the commoner species of mosquito cannot convey the organism of human malaria.

Confirmation and Application of Major Ross' Discovery.—Major Ross had not to wait long for the confirmation of his work. Dr. C. W. Daniels, of the British Guiana Medical Service, as a member of the Malaria Commission, was sent out to India that he might make himself acquainted with Major Ross' researches. In his report, about to be submitted by the direction of the Colonial Office to the Secretary of the Malaria Investigation Committee of the Royal Society, Dr. Daniels confirms Major Ross' discovery of the propagation of the *proteosoma* by mosquitoes.

In Italy, Professor Grassi and Drs. Bignami and Bastianelli, after receiving reports and

specimens from Major Ross, have published* their success in following the development of two of the parasites of human malaria in a species of mosquito (*Anopheles claviger*).

Kala-azar.—As the greater number of professional men who had studied *kala-azar* were of the opinion that it is a result of malarial infection, and as Captain Rogers had adduced some evidence in support of the belief that it is communicable in some way from man to man, it was believed that a study of *kala-azar* would throw some light on the problem of malarial infection. Accordingly, after he had succeeded in tracing infection by one of the so-called malarial parasites of birds from an infected bird through the mosquito to a healthy bird, Major Ross was deputed to Assam to investigate *kala-azar* on the spot. While this report is passing through the press, Major Ross has presented the outcome of his labours in a lengthy essay 'On the Nature of *Kala-Azar*.'

The questions which Major Ross set himself to solve were the following :—What is the nature of *kala-azar* ? If it is malarial, how can its communicability be explained ?

Major Ross begins his report with a description of the disease, which is a skilfully constructed mosaic of the opinions of the medical men who have had the most extended opportunities of studying its signs and symptoms directly. There are no prodromata. The onset of *kala-azar* is sudden ; the first symptom being fever which is introduced by a rigor or mere chilliness, is generally severe, may be continued, intermittent or remittent, and may last two or three weeks or even longer. This is succeeded by an apyrexial period lasting a week or two, to be followed by an attack of fever, similar to the first ; this in turn giving way to a fever-free period. There may be several alternations of fever and fever-free periods. In the meantime, the spleen always, and the liver in nearly every case, become enlarged and may be tender to the touch. Anæmia progresses with the illness, but varies in degree, extreme anæmia suggesting anchylostomiasis as a complication. Emaciation is progressive throughout.

Then follows a second stage characterised by extreme enlargement of the spleen and liver, and the persistence of a low form of fever which may last for months and may, or may not, be interrupted by attacks of high fever.

Dropsical conditions may arise ; bleeding of the nose is common ; and in some cases there is undoubted darkening of the skin.

The third stage is one of emaciation, during which the low fever disappears, the spleen and liver decrease in size, but emaciation and darkening of the skin persist, and weakness is extreme. Dysentery and diarrhœa are common intercurrent affections, and pneumonia may occur.

Death may take place during any of the stages—from high fever at the commencement of the illness, later from dysentery or diarrhœa or from exhaustion.

Shortly, then, the course of the disease may be divided into three stages ; the first characterised by recurrent attacks of high fever and rapid enlargement of the spleen and liver ; the second, by great enlargement of these organs and constant low fever ; and the third, by progressive emaciation.

The diagnosis of the disease in the first stage does not seem to be possible, as it does not differ from ordinary malarial fever ; in the second stage reliance is placed upon the failure to obtain good results from the administration of quinine, the history of several attacks among the family of the patient, and, probably, the great enlargement of the spleen and liver.

The pathology of the first stage is that of malarial fever ; but in the second stage Major Ross found that there were important differences from the conditions ordinarily held to be characteristic of malarial poisoning.

In cases in the second stage of *kala-azar* Major Ross found—

(*a*) that parasites were absent from the peripheral blood ;
(*b*) that parasites and generally black pigment were absent from blood taken during life from the spleen and liver ;
(*c*) that parasites and black pigment were absent from the spleen and liver in two out of seven autopsies ;
(*d*) that the temperature charts showed a fever apparently distinct from any of direct malarial origin ; but
(*e*) that yellow pigment was generally present in the liver.

---

* Rendiconti della R. Accad. dei Lincei—*Ulteriori ricerche sul ciclo dei parassiti malarici umani nel corpo del zanzarone.* Rome, December 22nd, 1898.

The points wherein *kala-azar* resembled ordinary malarial fever then are :—

(1) The occurrence in malarious places.
(2) The similarity of the symptoms of the early stage, any difference being in degree not in kind.
(3) The presence of the yellow pigment.

The points of apparent difference are :—

(1) The high death-rate.
(2) The apparent inefficiency of quinine.
(3) Absence of parasites and melanin.
(4) The persistent low fever, which is not amenable to quinine.
(5) The fact of communicability, which Major Ross regards as proved.

Major Ross then proceeds to discuss the apparent differences between *kala-azar* and malarial fever. He points out that the mortality from *kala-azar* is probably overstated, because the belief in its fatality is so strong that if a case recovers, it is no longer classed as *kala-azar* ; and that the actual mortality is probably not greater than the mortality from the severe malarial fever of many Indian terais. The failure of quinine to control the disease in its initial stage may be due to its not having been administered in sufficient quantity and at the proper time ; moreover, quinine occasionally fails in undoubted cases of malarial infection.

The absence of parasites and melanin is a more serious matter, and if it is to be accepted that *kala-azar* is malarial fever, it becomes nccessary to show that parasites and melanin may be absent in later stages of malarial fever. This leads Major Ross into a most suggestive sketch of the essential conditions in an attack of malarial infection remaining untreated. It is explained that the vast amount of recent literature on the subject has the defect, so far as the present argument is concerned, of dealing almost exclusively with the condition of the blood and organs in Europeans who have received specific treatment for the disease.

When the indigenous inhabitant of a malarious place is attacked, the invasion of parasites is very rapid, the resistant energy of the system is brought into play, and if death does not occur from the violence of the fever, the parasites are repulsed, being either exterminated altogether, or their numbers reduced below the point of toleration when they produce no symptoms in the host, and would not be discovered by the microscope in his blood save accidentally. When they are not exterminated, the parasites remain in the blood without giving rise to any sign of their presence, until a chill or some other interfering circumstance lowers the powers of resistance in the system of the host. The parasites then increase in number, and a recrudescence of fever ensues. Another period of quiescence follows, and the struggle is renewed again and again, until the resisting powers of the system, which become stronger on each occasion on which they are called forth, are able to render the blood of the host uninhabitable by the parasites.

But while this contest is going on, congestion of the abdominal organs has been established, and pigment has been deposited in them, so that by the time the sufferer's system has overcome the parasites, his spleen and liver have become enlarged and are laden with black and yellow pigments. After the parasites have disappeared, the black pigment is eliminated, but the yellow irritating pigment remains behind.

Regarding the absence of parasites, Major Ross quotes Laveran,* who states that when cachectics have been free from fever for some time, the examination of their blood does not as a rule reveal the presence of parasites ; and he cites the experience of Dr. Daniels in British Guiana, where he found parasites much less frequently in cases of enlarged spleen than in early cases of malarial fever.

The low fever of the second stage of *kala-azar*, in Major Ross' opinion, is due to the enlargement of the abdominal organs, is, in fact, symptomatic, and as it does not depend upon the presence of the organisms of malaria, the temperature curve of the fever does not resemble a malarial curve, and quinine is without effect on the fever.

In *kala-azar* then, in the first stage, we have the signs and symptoms of severe malarial fever with the deposition of black and yellow pigments ; in the second stage, there is the elimination of the back pigment, while the yellow pigment is retained, and there is a low fever due to the enlargement of the spleen and liver ; in the third stage, that of cachexia, the elimination of the black pigment is continued.

---

* Page 175, Traité du Paludisme, Paris, 1898.

Major Ross quotes Kelsch and Kiener's description of malarial fever, and shows that the conditions described by them as occurring in ordinary malarial fever are essentially the same as those occurring in *kala-azar*. He states, moreover, that *kala-azar* is practically the same as *kala-jwar* of the Darjeeling terai, and that a precisely similar fever occurs throughout India, especially in malarious localities.

The communicability of *kala-azar* does not of course differentiate it from malarial fever, if it is accepted that the latter is carried from man to man by suctorial insects. The spread of *kala-azar* in a village would depend upon the arrival in that village of a patient suffering from the disease, (in the early stage ?) and the presence there of the species of insect capable of carrying the parasite.

Perhaps the least satisfactory part of Major Ross' paper is his attempt to explain the cause of the special virulence of *kala-azar*. This must, he says, depend upon a special quality of the parasites or their occurrence in great numbers. He dismisses the first alternative without discussion, and suggests the explanation that an insect feeding upon the blood of a severely infected person would probably spread a severe form of infection.

Kala-azar then, according to Major Ross, is severe malarial fever, the distinctive later stages being due to the enlargement of the abdominal organs. The great mortality is due to the severity of the initial infection, aggravated by the conditions of life of the affected, and increased by the presence of anchylostoma and other intestinal parasites and the occurrence of dysentery in very many of the cases.

3196—6

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER FOR MADRAS FOR 1897.

(*Surgeon Lieutenant-Colonel W. G. King.*)

Vital Statistics.

The census population of 1891 for the Presidency of Madras was 35,641,828.* Registration was conducted in areas inhabited by 32,638,243.* During the year, there was a net decrease of the population by 92,118 on account of emigration from the ports of the Presidency. The "natural increase" of the population amounted to 108,320 during 1897.

No change was made in the system of birth and death registration. A proposal was made by the Deputy Director of Agriculture (Board of Revenue), to utilize the birth registers throughout the rural areas for purpose of checking vaccination. This proposal was also made by me in my report on the re-organization of the Vaccination Department, dated 23rd October 1891, embodied in G.O., No. 1066 L., dated 9th May 1892. The details for the effecting of this desirable change were under discussion at the close of the year. In all municipalities this has been in operation with good results since 1895 (*vide* G.O., No. 1502 M., dated 19th October 1894). The system not only aids vaccination, but forms a good check upon false registration; as the necessity for vaccination entails in due course the verifying of each birth reported.

Births in Rural Areas.†—862,846 births were registered in rural areas. This affords a birth-rate of 28·3 per 1,000, against 29·5 of the previous year, and 27·3—the average of the preceding five years. Registration results are much vitiated in this Presidency in areas under zemindars, in consequence of the services of the village officials responsible for the statistics not being under the full control of the Revenue officers. The birth-rates for Muhammadans was 25·4, for Hindus 22·3, for Native Christians 23·7 per 1,000 of their respective populations in the Presidency including municipal towns. 104·0 boys were born against 100 girls. The previous year's percentage was 104·8.

A decrease of the birth-rate was registered in fifteen districts. There is no reason to regard this result as due to a falling off in the efficiency of registration having regard to the known increased care taken in this matter, and the fact that, although the total birth-rate is less than the previous year, it is above the average for the previous five years, and that no falling off had occurred in the death-rate. The decrease is doubtless due to a continuation of causes noted in paragraph 19 of the previous year's report, together with the influence of diminution of food supply in certain areas, and deferred marriages owing to the unfavourable state of agricultural prospects.

Births in Municipalities.—The total average birth-rate for the 59 municipalities in this Presidency was 34·4 per 1,000, against 36·1 of the previous year, and 34·0—the average of the five previous years. A decline of birth-rates occurred in 41 municipalities. The rates are so markedly incorrect in Chicacole, Berhampur, and Dindigul, that it is obvious that careless registration has had much to do with the result. The attention of the Chairmen of these Councils has been invited to this subject. In eight municipalities the birth-rate was over 40, in 14 over 35, in 20 over 30 per 1,000.

The following table contrasts the rates obtained during 1897 with those for the previous five years :—

Years.	Birth-rate per 1,000 of population.	Years.	Birth-rate per 1,000 of population.
1892	31·4	1895	35·3
1893	34·1	1896	36·1
1894	33·2	1897	34·4

* These figures include Europeans and Eurasians.

† Includes rural towns of 10,000 inhabitants and more, and excludes Municipal towns.

Taking into consideration the conditions suggested above, there is no reason to think there has been a falling off of efforts towards accurate registration, the total birth-rate being 0·4 above the average for the previous five years. If the three municipalities where it is suggested carelessness exists be excluded from the calculation, the birth-rate for the year shows an increase of 0·5 above the average for the previous five years.

Deaths in Rural Areas.—The total death-rate for the Presidency was 24·8 per 1,000, which is the highest recorded since 1891. This is 5·1 per 1,000 above the average for the preceding five years, and 4·8 above that for the preceding year. In 15 districts, the average for the five years and the rate for the preceding year were exceeded. The increased rates were most evident in the seven districts in which famine was officially recognised as existing. In Malabar and South Canara, where scarcity was experienced for a certain period by the poorer classes, but was not considered of such a type as to demand special aid from Government, the mortality also was above the average. In these districts, the death-rate under all diseases recognised by registration underwent an increase. In both, fevers were unusually severe. The rise in the total death-rate was, however, chiefly influenced by the large numbers of deaths registered under cholera and small-pox in Ganjám, and cholera in Malabar and Tanjore. The following table shows the death-rates and incidence of death causation during the last seven years :—

Years.	Death-rate per 1,000 of population.						
	Cholera.	Small-pox.	Fevers.	Dysentery and Diarrhœa.	Injuries.	All other causes.	Total.
1891	2·8	1·2	7·3	0·8	0·3	9·0	21·4
1892	2·3	1·3	8·3	0·7	0·4	8·6	21·6
1893	0·9	0·8	7·6	0·5	0·3	8·4	18·5
1894	1·2	0·3	8·0	0·6	0·3	8·9	19·3
1895	0·6	0·2	8·2	0·5	0·3	9·2	19·0
1896	1·4	0·3	7·9	0·6	0·3	9·5	23·0
1897	4·4	0·7	9·0	1·0	0·3	9·4	24·8

94·2 women died against 100 men. Last year, the figures were 94·5 women against 100 men. The infantile death-rate per 1,000 of births was 164·5, against 156·9 of the previous year.

Deaths in Municipalities.—The total average death-rate for the 59 municipalities was 33·3 per 1,000, being an increase of 2·6 above the previous year, and 2·5 above the average for the five previous years. The infantile death-rate was 223·1 per 1,000 of births, against 232·9 per 1,000 of the previous year. The death-rate amongst adults of over 50 years of age was 61·8 per 1,000 of the population of that age, against 57·6 per 1,000 of the previous year.

Chief Diseases.

Cholera.—A total of 143,445 deaths from cholera were reported in the Presidency, being at the rate of 4·4 per 1,000 of the population, against 47,847 deaths of the last year, or 1·5 per 1,000 of the population. The mortality in Ganjám and Malabar was very heavy from this cause, namely, 15,553 and 27,533, respectively. In both districts the sanitary efforts made cannot be described as adequate, but, on the other hand, the predisposition of the population was increased by conditions of scarcity. Indeed, the medical officers of both districts maintain that diarrhœa of a character simulating cholera was due to the eating of unfit food by the people.

In municipalities the total deaths from cholera amounted to 10,258, or at the rate of 4·8 per 1,000 of the total population.

Although owing to inadequacy of staff not much can be done in this direction, all local authorities are fully aware of the importance of strict attention to the careful destruction of choleraic matter, and protection of water-supplies from contamination. The disinfection of water supplies, when small, by means of permanganate of potash, and, when large, by lime and alum, is freely practised. The latter process is so similar in its rationale to that secured by use of the clearing nut (the *strychnos potatorum*) that I have never heard of opposition to its employment. The red colour produced by the permanganate of potash, which is specially advised by Mr. Hankin, is occasionally objected to; but, on the whole, both the people and the medical officers regard its use favourably in most districts. Tables issued from this office allowing of quick calculation of quantities to be employed of these disinfectants, have been long in the hands of Certificated Sanitary Inspectors and medical subordinates.

Small-pox.—A total of 21,678 deaths from small-pox occurred in the Presidency—equivalent to a death-rate of 0·7 per 1,000.

Ganjám suffered most severely from this disease, no less than 14,515 deaths being registered under this head. The following extract from the District Medical and Sanitary Officer's report sufficiently explains this result, when combined with the fact that the people must have wandered from village to village in search of employment, during the early period of the famine:—

"The presence of distress in the district has no doubt had much to do with the widespread "prevalence of cholera and small-pox; but as regards the latter, I am of opinion that the small-"pox epidemic would not have assumed such proportions had vaccination been made compulsory "in this district. To assist the permanent staff six temporary probationary vaccinators were "employed for nine months.

* * * * *

"It must also be noticed that the customs of the Uriyas greatly tend to spread an outbreak "of small-pox. The infected rag and mats, &c., are collected and thrown into the open and the "soiled clothing, &c., washed in tanks used for drinking purposes, thus disseminating the disease. "Several instances have been brought to notice where the bodies of people dying of small-pox "have not been buried, but deposited on tank bunds or dry bed of tanks and other convenient spots. "This matter was brought to the Collector's notice and orders were issued to prevent this procedure. "I fear it will not be possible to entirely stop this custom, nor will small-pox be kept in check until "vaccination is made compulsory throughout the district. Zemindary villages are very dirty and the "Uriya people are very dirty in their habits, and there is very little control in a sanitary sense kept "over them."

Malabar, which so long headed the list, does not now exhibit the usual mortality from small-pox. The vaccination staff has been considerably increased, and much attention has been paid to perfecting the working of the department in this district. The result is apparently a steady diminution of the deaths from small-pox, from 12,068 in 1893 to 43 in 1897. Of course, this *post hoc propter hoc* argument is open to the criticism that a large number of the population are now really protected not by vaccination, but by previous attacks of small-pox. Time alone can, of course, prove which is the real factor. In the meantime, there is undoubtedly still much room for improvement of organization of the Vaccination Department in Malabar, to enable it to suit the local peculiarities of distribution of villages and residencies.

Fevers.—The total deaths from fever in the Presidency amounted to 292,292—equivalent to a rate of 9·0 per 1,000 of population, against 260,769, or 8·0 per 1,000 in the previous year. The excess deaths occurred in June and subsequent months. Up to that month, the mortality from this cause had been less than in the previous year. The comparative freedom in the early part of the year must be ascribed to the diminished soil moisture proving inimical to the propagation of the malarial germ, in consequence of failure of the north-east monsoon of the previous year: this was followed, on access of moisture with the south-west monsoon, in the presence of a population rendered susceptible to malaria owing to diminished food-supply, by a mortality greater than normal under this head.

Surgeon-Major Ross, with whom the study of malaria is a speciality, made several important advances towards the completion of proof of what has hitherto been a mere hypothesis as to the part borne by the mosquito in propagating malaria. He has been since placed on special duty under the Director-General.

In the Cuddapah district, the diminution of malarial fever noticed in the last year's report continued up to the month of April 1897. Up to this time, 2,119 lives had been saved when the average death-rate for the preceding five years is regarded, but, subsequent to this period, an increase in the fever incidence set in; so that at the end of the year there was an excess under this head when compared to the previous year, but still the rate was 1·5 below that for the five years' average. The influence of famine conditions doubtless aided this result.

During the year, the Sanitary Engineer's Department in the course of borings, preliminary to a drainage scheme for the Cuddapah town, showed that the soil rests upon a thick layer of clay, beneath which again is found the water derived from the numerous springs, which apparently flow beneath the town from the adjoining range of hills. This has been advanced as a satisfactory reason why a sub-soil drainage scheme should not be attempted side by side with the sewerage scheme. The argument, however, seems to me to assume a continuity of this clay layer which is not certain in nature, and has, as a matter of fact, been artificially disturbed all over the town by the digging of wells allowing the sub-soil water under pressure to rise above the clay, and to ignore the property of clay which, whilst not readily permitting the direct passage of water through it, nevertheless must, by capillary attraction of the soil above, yield vast quantities of moisture.

In the case of Kurnool town, which shows the very heavy increase in the death-rate of from 13·5 to 21·7 per 1,000, under this head, the probability is that the disturbance of the soil during the excavations for the water-works throughout the town has had much to do with the result ; as foreseen by me, would be the case (*vide* page 6 of my Inspection Note embodied in G.O., No. 480-M., 10th April 1894) irrespective of the increased susceptibility of the population owing to famine conditions.

Dysentery and Diarrhœa.—The death-rate under dysentery and diarrhœa was 1·2 per 1,000 of the population, against 0·7 per 1,000 of the previous year. The excess was contributed to by 13 districts, of which seven were formally recognized as suffering from famine, whilst in the others undoubtedly a considerable grade of distress was undergone :—

Anantapur,	Kurnool,	South Canara,
Bellary,	Madura,	Tinnevelly, and
Cuddapah,	Malabar,	Vizagapatam.
Ganjám,	Nellore,	
Gódávari,	North Arcot,	

In the following towns where the incidence was over 1·5 per 1,000 greater than in the former year, the explanation above given also applies :—

Anantapur,	Tellicherry,	Cuddalore,
Bellary,	Cochin,	Mangalore,
Adóni,	Nellore,	Máyavaram, and
Cocanada,	Ongole,	Bimlipatam.
Ellore,	Gudiyáttam,	
Kurnool,	Tirupati,	

The continued presence of diarrhœa and dysentery in Coonoor, combined with the high death-rate from general diseases, dictates the necessity for early action in reference to the water-supply of the town which, as I have shown in former reports, is subject to pollution. The municipality has now before it for consideration a sound water-supply scheme ; if it does not wish the fame of Coonoor as a sanitarium to pass away from it for ever, it will endeavour its best to finance it without delay.

Comparative statement of incidence of special diseases.—The following table contrasts the chief points discussed in this, and in the foregoing section, with reference to the Presidency as a whole, in a convenient form :—

	Birth-rate per 1,000 of the census population.	Death-rate per 1,000 of the census population.						
		Cholera.	Small-pox.	Fevers.	Dysentery and diarrhœa.	Injuries.	All other causes.	Total.
1892	25·1	2·3	1·3	8·3	1·0	0·3	9·0	22·3
1893	27·0	1·0	0·8	7·7	0·7	0·3	8·8	19·3
1894	27·7	1·3	0·3	8·0	0·7	0·4	9·3	20·0
1895	29·1	0·6	0·1	8·3	0·7	0·3	9·6	19·6
1896	29·9	1·5	0·3	8·0	0·7	0·3	9·8	20·6
1897	28·7	4·4	0·7	9·0	1·2	0·3	9·8	25·4

Sanitary Works.

Municipalities.—In conformity with the amended Municipal Act (Act No. IV of 1884 amended by Madras Act No. III of 1897) in certain municipalities having a total income of over Rs. 30,000, the question of employing Secretaries to aid the unpaid Chairmen has engaged a good deal of the attention of councils.

It remains to be seen whether the arrangement, which was a compromise for the original proposal of having paid Chairmen, will prove of advantage in administration. It would at least seem essential if the incumbents of the appointment are to be more useful than the old manager class of men, that they should be required to pass examinations in certain minor engineering subjects, and possess a certificate in sanitation. A further sequence of the introduction of the new Act has been a demand for issue of model forms for licenses for offensive or dangerous trades. These have been prepared, and will be issued to municipal councils shortly. As valuable additions have been made in the District Municipalities Act for regulating milk and food supplies, and conditions under which the opening of new water sources, burial grounds, &c., is permitted, there is every reason to hope that the demand, which has been quite spontaneous, represents a determination to meet the requirements in necessary sanitary matters with firmness.

The accompanying statement exhibits the expenditure on sanitary improvements during the year. In perusing this, it must be remembered that the period 1896–97 is for the whole official year, whereas that for 1897–98 is but for nine months of the year :—

	1896–97.		Rate per cent. of expenditure to total allotment.	1897–98.		Rate per cent. of expenditure to total amount.
	Amount sanctioned.	Amount expended.		Amount sanctioned.	Amount expended in nine months ending December 1897.	
	Rs.	Rs.		Rs.	Rs.	
For conservancy	5,82,010	5,52,307	94·9	6,50,524	4,63,861	71·3
For improvement of village or town sites.	2,96,941	2,67,875	90·2	2,78,375	1,63,353	58·7
For improvement of water-supply, cleansing, repairing, and construction of tanks and wells.	4,29,440	4,72,237	109·9	9,48,885	4,07,095	42·9
For sanitary arrangements during fairs and festivals.	36,950	35,314	95·6	13,760	10,085	73·2
For construction and repair of markets and slaughter-houses.	47,158	28,138	59·7	40,111	13,766	34·3
For other sanitary objects...	1,23,043	1,01,361	82·4	1,20,618	79,237	65·7
Total	15,15,542	14,57,232	96·2	20,52,273	11,37,397	55·4

Having regard to the proportion spent up to the end of the calendar year, there is little reason to believe that funds have been allowed to lie idle. The expenditure under conservancy, which amounted within the period stated to 71·3 per cent. of the allotment, shows that conservancy is conducted in municipalities with slightly increased vigour. No opportunity, in reporting during inspections as to the condition of municipalities, has been neglected by myself or Deputy to impress upon municipal councils the absolute necessity there is for improvement in this the A B C of sanitation. Similarly, in reviewing each proposed budget, the attention of Government has been invited to the necessity for improvements. As with most sanitary reforms in this country, some time has elapsed in securing the desired ends, but I think the statement of method of expenditure of funds shows that many councils now recognize their shortcomings in

this respect. Urgent reminders as to preparations for plague have doubtless also influenced results. One of the most difficult matters to bring home to councils has been the fact that with the capacity of plant at their disposal and the number of trips per cart feasible, it was impossible for them to do more than make very perfunctory attempts at removal of night-soil and rubbish. Curiously enough conviction on this point has always been much more easy with respect to rubbish removal than night-soil. The statement, however, shows that a large number of night-soil carts have been added this year to the municipal plant. Municipalities to the north of the Gódávari river form remarkable exceptions to this statement; they busy themselves in evolving amazing reasons why it is preferable to use open baskets borne by men or women, instead of employing night-soil carts.

In the reorganization of the staff also a satisfactory change has occurred. The effect of the attempt to furnish supervising staffs on the lines of quality instead of quantity is exhibited by the decrease of the uneducated class of "overseers" and peons, in favour of an increase in Sanitary Inspectors, all of whom, if newly appointed under G.O., No. 4-M., dated 4th January 1897, must possess qualifying certificates.

No advance beyond that reported last year has been made in respect to sewage farming. Sewage filtration continues to be satisfactorily practised at Vizagapatam and Vizianagram.

The "ærated household sewage filter," mentioned in my report for 1895, continued to work most satisfactorily at Bellary during the year; as it was animadverted upon by the Army Sanitary Commission, I have not sought to put it further into use. I may, however, state that it continued to discharge the sewage from the large household served, in a condition pure to sight and smell; at the top of the filter a thin layer of deposit formed, almost devoid of odour. The filter continued to work without a renewal of the material successfully for over fourteen months. The principle of filtration of sewage was also carried on at the Pushkaram festival at Bezwada, and at the Mahamagham festival at Kumbakónum. In the latter town, owing to absence of any sewerage system, pools of sewage forming suitable breeding grounds for masses of mosquitos are common in every lane. Grasping the principle of sewage filtration exhibited to them at the Maghamagham festival, under the superintendence of Surgeon-Captain Vickers, the council has sent, for approval as a temporary measure, a scheme for sewage filtration at various convenient parts of the town, united with disposal of the crude sewage upon suitable plots under cultivation. In the meantime, the sewage of a largely inhabited town is being disposed of satisfactorily by the temporary filter made on this occasion.

The rules for regulating the sanitary action of municipalities during cholera epidemics (G.O., No. 1536-M., dated 9th September 1896) continued to receive far less punctual observance than consistent with success in combating a disease where promptness of action is essential. The loop-hole given in the regulations that, with the consent of the Collector, the staff may be less than laid down in the rules, is freely utilized, with the effect of rendering results very indifferent. Where the rules have been promptly obeyed, their influence in saving life and arresting cholera epidemics is indubitable.

District Boards.

The advent of the amended Act for Local Fund areas has been foreshadowed, by the circulation of the draft Bill to all authorities for criticism and suggestions. As remarked in former years, until the hands of the Local Fund bodies are strengthened by an Act that will give them money and power for appointing sufficient staff, and for securing sanitary ends by legal measures, it is impossible to expect a very rapid rate of sanitary advance. One of the most glaring defects is the absence of a sanitary staff for employment during epidemics. Huge areas of the rural tracts are still unprovided with any one capable of directing measures during epidemics, and of even the small menial staffs that exist. The importance of the employment of Certificated Sanitary Inspectors for the purpose has been repeatedly brought by me to the notice of District Boards. But, as might be expected from their constitution, District Boards are slower than municipalities in recognising the desirability of early action. A lamentable instance of the want of an organization capable of dealing with epidemics, is exhibited in the fearful mortality that occurred in the districts of Malabar, Ganjám and Tanjore from cholera during the past year. Most District Boards have, in connection with reviews by this office on submission to Government of their budgets, now got this question before them, and certain of them have made proposals on the subject.

During the year, four Certificated Sanitary Inspectors were employed in Kistna, two in Trichinopoly, and one in Tinnevelly.

Nine villages were converted into unions during the year—making a total of 378 existing unions. This implies at least that in these villages some distinct efforts towards the more simple dictates of sanitation are being made.

The allotment for sanitation was 8·4 of the total estimated income, being the same as in the previous year. Under conservancy, the allotment underwent an increase. In the case of Malabar, South Canara and Ganjám, the allotments were particularly unsatisfactory as to amounts. Government has, in response to my opinion on the budgets, invited the attention of the Boards, but without avail. In the case of Malabar and South Canara, fixed local opinions exist as to there being no necessity for taking action—it being especially an article of faith that men who live for the greater part of their service on the east coast of the Presidency cannot understand the great advantages resulting from the habits of the people living in "Parambas," and their having independent water-supplies. That, however, sanitary supervision is just as necessary here as elsewhere, is proved by the following extract from the Annual Report by the District Medical and Sanitary Officer, Surgeon-Lieutenant-Colonel Wilkins :—

"During the monsoon, in addition to cholera, there was an epidemic of enteric fever in the town "and district, among the natives chiefly. There were 18 cases, in all, among the Europeans and "Eurasians. 128 cases were treated by myself and the medical subordinates in the district, and two "native qualified practitioners treated 15 cases. It is a mistaken idea to believe that natives have an "immunity against enteric fever. I have had under my care undoubted cases showing every "complication. In fact, from enquiry, I believe the disease is epidemic in parts of Malabar and its "prevalence greatly depends on the sub-soil water. It usually begins to show itself about the "middle of the rainy season, when the sub-soil water is almost on a level with the surrounding "ground, and it lasts for quite four months or longer, until the water sinks to 12 or 16 feet below "the surface. I attribute this chiefly to the practice here of having pits in the compounds for "latrines, as also in many cases, to the burying of the dead, among some classes, in the same "compound, and when one considers that these are all within 10 or 15 yards from the drinking-"water wells, it is not a matter of surprise that the disease shows itself in the rains and it is no "wonder then that enteric cholera and other water-borne diseases are constantly present in Malabar.'

Personal Proceedings.

On the 19th December 1896, I started upon a tour in the famine-affected districts and continued in camp without intermission till the 8th March 1897. During this time, I was engaged in passing from village to village, with the object of not only studying the condition of the people and the necessity for affording them relief in various doubtful areas, but of gathering data in respect to their normal food supply, and watching the influence of the famine rations. I found it necessary to advise Government that the famine rations C and D were unfit for purposes of labour, and represented that the B ration was the least that could be used with safety. In these contentions, I received the cordial support of the Famine Commissioner, Mr. W. J. H. LeFanu, an officer of exceptionally large famine experience. In offering this advice, I was perfectly well aware that my views would not coincide with those prevalent in other provinces. But a tour in the famine-affected districts of Bombay and study of methods in other provinces, showed me that the different wording and interpretation of the codes, and various items in the administration of relief, contributed to produce different results, under nominally the same conditions. It seems to me perfectly clear that when the lower grades of diets are considered, it is impossible to show that a native can live "in health and strength" upon any less than a European, when the amounts of nutriment are reduced proportionately for the respective weights of these races. It is equally impossible for him to live without vegetable diet—as the famine diets practically presuppose—without exhibiting symptoms of scurvy.

From a review of all attendant circumstances, I believe the adoption of the policy of giving a diet just sufficient for requirements, and yet not vitiated by the indubitable deficiency offered by the C diet, really proved a source of financial benefit, in that the enormous indirect charges incurred in other provinces were in Madras rendered unnecessary. At any rate, it served the required purpose of saving life in the midst of distress, that, at certain parts of the year, was as acute as during the famine of 1877, when many thousands lost their lives in spite of the practically unlimited expenditure of money in attempting to save them, after the error of scanty diet had been ascertained too late for effective action. I would add that the conclusions to which I invited the attention of Government were not founded upon mere theory ; but that wherever I went I took with me scales and weights, and daily undertook experiments with both cooked and uncooked food of the labouring classes and famine workers, &c., &c.

In March, I proceeded to Rajahmundry Jail for the purpose of investigating an epidemic of cholera which had occurred there. I returned on the 28th March to headquarters. On the 8th April, I proceeded to inspect the railway observation camps at Pódanúr and Arkonam. On my return, I was required by Government to proceed to Ennore, where unusual prevalence of fever had disabled the Salt and Abkárí Department staff, and there was doubt as to its nature and origin. It proved to be of the malarial type. From Ennore, I proceeded to the Coimbatore Jail, where also an epidemic of cholera had taken place. By the 21st April, I was again ordered to proceed to Rajahmundry Jail to investigate with the Surgeon-General certain matters in connection with the general ill-health of the prisoners. In the intervals of work, I had when at headquarters afforded my customary aid to the Professor of Hygiene, by undertaking the teaching of the Certificated Sanitary Inspectors' class by out-door demonstrations.

In June, I was detailed by Government to meet in Madras Drs. Lorans and Lawson, the latter in the function of Plague Commissioner. He was, unfortunately, unable to tell me precisely what date he would arrive, and when this took place, was incapable of fulfilling work, as he was laid up with fever. On his departure, I left for Coonoor with reference to inspection of certain grave-yards. I then proceeded to Cuddapah to meet Mr. Higham, who had been deputed by the Government of India to inspect famine works in this Presidency. I inspected with him the famine works at Cuddapah, and then proceeded to Adóni with him. Here I met the Famine Commissioner, and proceeded on tour with him till the 27th July. In August, I toured in the famine-affected districts of Bombay. In September, I inspected certain villages and famine works in the Adóni, Anantapur and Jammalamadugu taluks. In October, an imported case of plague having occurred in Madras, as soon as matters were arranged locally, I proceeded again to inspect the camps at Guntakal and Arkonam. In November, I proceeded to Berhampur with reference to the fixing of the boundaries of the cantonment, as a member of the military committee for this purpose. On my return, I investigated suspicious cases of plague that had been reported in the North Arcot district. These proved to be instances of anthrax in the human being, of which four instances in various localities in this Presidency have come to light during the present year. In December, I made a tour by road through certain of the famine-affected taluks in the Bellary district, with the object of ascertaining the condition of the villagers at the end of the administration of relief. Attendance upon the Famine Conference at Madras closed the year. There was thus no time to attend to routine of inspections of municipalities, and, this having been represented to Government, it determined that the demands of famine and plague should first receive my attention (G.O., No. 1545-L., Mis., dated 15th August 1897). However, matters connected with sanitation and vaccination were brought to notice of village and revenue authorities—more especially with regard to water-supplies—when inspecting villages.

During the year, I fulfilled 6,296 miles by road and rail, and was absent from head-quarters a total of 196 days. Irrespective of routine office work, which was heavy on account of famine and plague arrangements, I dealt with 143 papers referred to me by the Sanitary Board.

With reference to the continued presence of plague in the other parts of India, Government accepted my advice against any attempt at quarantine by land or sea for healthy persons or ships. This policy anticipated practically the line of action advised by the Venice Convention. The result has been the weaving of a system of "observation," effected by all local authorities and the Police, throughout the Presidency, in conjunction with special points of observation on railways. Although in practice there was no want of evidence that it was favoured by the element of chance, this system proved itself worthy of confidence during the only known instances of importation of plague during the year. A racing party that had visited Poona was affected. A case of plague from amongst them was taken from the train at Guntakal, and another at Arkonam. A third case underwent incubation in Madras whilst on the observation list. He died of the disease. In their eagerness for ascertaining the conditions in this—to them new—disease, a *post-mortem* was conducted by two medical officers ; one had an abrasion in his hand, and was duly affected with symptoms indistinguishable from plague ; an attendant pricked his hand during the *post-mortem*, and died of this disease. This menial absconded from the hospital, but was luckily traced by the then Health Officer of Madras—Dr. Cook. Under the system of observation in force, the whole of the persons connected with the outbreak were readily traced and carefully supervised. In the various steps requisite, I was in close communication with the President of the Municipality of Madras, who was prompt and decisive in all arrangements made. At Guntakal and Arkonam, every possible precaution was taken to prevent further spread from these cases intercepted there.

The man received at Arkonam ultimately recovered. However much, therefore, Madras may have been favoured by climatic conditions inimical to the spread of the plague microbe, and by amount of passenger traffic with provinces that had been affected being limited, there can, I think, be no shadow of doubt that the sanitary measures put in force by Government did, in these instances, effectually prevent what might reasonably have been looked for, namely, the epidemic spread of plague from imported cases. For example, had not, under the "observation system," there been available lists of all persons connected with this infected party, it would not have been possible, as was actually done, to ascertain that each individual had passed safely throughout the ten days incubation period. Whatever there may be in store for this Presidency in the future, it is, humanly speaking, certain that the measures adopted on this occasion did, at least, defer its fate. Whilst fully admitting the conditions I have noted as favouring this Presidency, I cannot but think that it is a matter for content that safety has been attained through so many months of doubt, without the discomforts to the public and losses to trade incidental to a system of "land quarantine," which, I was strongly urged by the Government of India Plague Commissioner to believe, was the only safe course to pursue.

The principle of using Mons. Haffkine's inoculation as a prophylactic measure was early recognized by Government as likely to be of much utility, and since October 1897, a reserve of his "Vaccine" has been kept in store, with necessary syringes for instant issue, in the event of an outbreak—as an addition to ordinary sanitary precautions.

Sanitary Engineering (1897).

The Sanitary Engineer visited 10 towns, and the Assistant Engineer 8, against 13 and 11, respectively, in 1896. Some of these towns were visited more than once. During the year surveys, either for water-supply or drainage, were completed for 2 municipalities, and were in progress in one municipality as against 7 in 1896, and additional levels for water-supply were taken for 2 municipalities. Water-supply schemes for Negapatam and Coonoor, estimated to cost Rs. 9,89,680 and Rs. 1,13,800, respectively, and drainage schemes for Cuddapah and Tanjore (portion), at an estimated cost of Rs. 5,40,000 and Rs. 33,440, respectively, were submitted to the Sanitary Board during the year. Preliminary reports and alternative estimates amounting to Rs. 1,70,000 and Rs. 1,28,000 for the water-supply of Ellore, and estimates for the extension of the infiltration gallery at Cuddapah, and extensions of water-supply at Conjeeveram and Trichinopoly were also submitted. The estimate for Cocanada water-works was also revised. At the request of the Kumbakonam Municipality, a rough estimate amounting to Rs. 25,000 for the sewerage of a portion of the town called the Putnul block was furnished. The Municipal Council of Madura was furnished with plans, and an estimate amounting to Rs. 5,200 for the extension of pipe lines to Teppakolam. At the request of the Sanitary Board plans and estimates amounting to Rs. 1,031 and Rs. 1,293 were prepared for the improvement of the Penta main drain in Tirupati. Schedules and specifications for the execution of water works in Cocanada, Tirupati, and Vizagapatam were prepared and furnished to the Public Works Department. The water-supply works for the towns of Kurnool and Conjeeveram which were in progress during the previous year were completed during the year, and handed over to the Municipal Councils concerned. The services of the Assistant Sanitary Engineer to Government were temporarily placed at the disposal of the Pudukkottai Durbar, for the preparation of a scheme for the improvement of the water-supply of the town. Twelve new type designs for various sanitary works were prepared during the year, and were approved of by the Sanitary Board. Advice was given to the Sanitary Board in respect to 46 municipal and 68 local fund schemes.

The works at Madura, Kurnool, Dindul, Trichinopoly, Tanjore and Adoni were inspected by the Sanitary Engineer during the year. The Inspector of Steam-boilers and Prime-movers visited the pumping stations at Cuddapah, Trichinopoly, Tanjore, Madura, Dindigul and Conjeeveram, and made a complete inspection of the whole of the engines, boilers and pumps. Detailed reports were forwarded to the councils concerned, with a request to carry out the necessary repairs.

Sanitary Board.—The Sanitary Board continued to work under the constitution framed by the Local Government in 1896. During 1897 several water-supply and drainage schemes were examined and submitted to Government by the Board.

The question of bacteriological investigation engaged the attention of Government during the year, and the Sanitary Board was asked for information as to the amount of

work that would be required of a bacteriologist by the Board in connection with actual local requirements apart from general and theoretical researches. The Sanitary Board endorsed the views of the Sanitary Commissioner who entered very fully into the nature and scope of the work that a bacteriologist might be expected to undertake. It was pointed out that the labours of such an officer would cover a wide field, and would embrace the bacteriological examination of all suspected sources of contamination from which disease, affecting the population, might arise, so as to identify the source and the nature of the poison. A bacteriologist might also by preliminary investigations determine the value of certain classes of sanitary works before they were undertaken, and thus prevent mistakes and save useless outlay. The Government arrived at the conclusion from the consideration of these and other opinions that there was a large scope for a bacteriologist in this Presidency, and advised the Government of India accordingly.

The Board was also consulted by Government regarding rules regulating the formation of towns in the vicinity of railway stations, and they submitted a set of rules for adoption. The Board also scrutinized during the year plans and estimates for 185 sanitary works, of which 54 were for municipalities and 131 for Local Fund boards. The total estimated value of the projects amounted to Rs. 11,91,201–10–2.

3196—6

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER FOR BOMBAY FOR 1897.

(*Surgeon Lieutenant-Colonel J. W. Clarkson.*)

General Population.

European and Eurasian Vital Statistics.

By the census of 1891 the European civil population in the Bombay Presidency, exclusive of cantonments in quasi-foreign territory, numbers 18,486 persons. During the year 1897, 257 births and 290 deaths were recorded against 294 and 303 in 1896, respectively—a birth-rate of 13·90 per 1,000 against 15·95 in 1896 and a death-rate of 15·69 against 16·40. By sexes 119 males and 138 females were born against 161 and 133 respectively in 1896, and as regards deaths, 170 males and 120 females died against 188 and 115 respectively in 1896.

The Eurasian population numbers 8,519 persons by the census of 1891, and during the year 1897 the births amounted to 134 against 156 in 1896 and the deaths to 240 against 195—the rates respectively of 15·73 per 1,000 against 18·31 in 1896 and 28·17 against 22·89. Of those born, 72 were males and 62 females against 99 and 57 respectively in 1896, and as regards deaths 123 males and 117 females died against 111 and 84 respectively in 1896.

A table is appended showing the European and Eurasian population in each collectorate and the births and deaths for the year 1897 compared with the births and deaths in 1896, and another table following shows the deaths by causes and the ratios in 1897 compared with 1896 :—

	Other Causes ...	4	*	2	*	4	*	1	*
	Total ...	5	*	3	*	5	*	2	*

* As the population for the cantonments in quasi-foreign territory is not obtainable, the ratio of deaths cannot be worked out. The deaths from plague are included under fevers. Figures in block type denote deaths from plague.

Of the 10 deaths registered from cholera among Europeans, 4 occurred in the collectorate of Khándesh, 3 in the City of Bombay, 2 in Sátára and 1 in Ahmednagar. Of the 3 deaths from cholera recorded among Eurasians, 2 took place in the collectorate of Sholápur and 1 in Khándesh.

From small-pox only 1 death occurred among Europeans in the collectorate of Khándesh.

In the City of Bombay during the year under report there were 20 deaths recorded from Plague among Europeans against 6 in 1896.

In the collectorate of Thána the one death recorded among Europeans during the year was due to plague.

Among the Eurasians there were 44 deaths recorded from plague, of which 39 took place in the City of Bombay, 2 in the collectorate of Sholápur, 1 in Násik, 1 in Poona and 1 in Surat.

Native Population—Vital Statistics.

Births.—In the Presidency of Bombay, including Sind, during the year 1897 there were 629,693 births registered against 691,847 in 1896. The recorded births for the year under report were less by 62,154 than the number registered in the previous year

and also less by 23,163 than the mean of the preceding ten years ending 1896. By sexes there were 327,573 males and 302,120 females against 359,097 and 332,750 respectively in 1896.

The following table shows the number of births registered in each year from 1887 to 1897, their ratios per 1,000 of population and the proportion of males to females :—

Years.	Population.	Number of Births registered.			Ratio per 1,000 of Population.			In every 100 Births there were		For every 100 male Births the females were

Mean for 10 yrs.	17,873,732	339,382	313,474	652,856	18·99	17·54	36·53	51·98	48·02	92·37
1897	18,820,346	327,573	302,120	629,693	17·41	16·05	33·46	52·02	47·98	92·23

The recorded birth-rate for the year was 33·46 per 1,000 of population against 36·76 in 1896 and a mean of 36·53 for the previous ten years.

Of the 24 collectorates and districts the number of recorded births in 1897 was higher than in 1896 in Thána, Thar and Párkar, and Upper Sind Frontier. The remaining collectorates show a decrease as compared with 1896, for which plague and famine sufficiently accounts. In Bombay City the birth-rate usually low is rendered still lower by plague and the exodus occasioned by it.

The Deputy Sanitary Commissioner, Central Registration District, remarks that the large decrease in the number of births (30,059) in the Central Registration District is due to the effect of famine and plague.

The Deputy Sanitary Commissioner, Sind Registration District, remarks that there has been monthly decline in the register of births until April 1897, when the plague was making its ravages. From May upwards, when the plague showed signs of disappearance, the total number of births increased monthly up to October, by which time Sind was free from plague.

The recorded birth-rates among the urban and rural populations of the Presidency were 24·85 and 34·66 against 29·61 and 37·76 in 1896. Except in the collectorates of Ratnágiri, Dhárwár, Bijápur, Kánara, Kaira, Panch Maháls, and throughout Sind, the birth-rates were higher among the rural than in the urban population.

Out of 56 towns in the Presidency, 18 had a birth-rate exceeding 40 per 1,000. Poona, Thána, Bombay, Násik and Alibág have very low birth-rates.

Deaths.—Among the civil population in the rural, town and cantonment circles in the Presidency 749,916 deaths were registered during the year 1897. In 1896, 596,472 deaths or 153,444 less than in 1897 were recorded.

The following statement shows the number of deaths recorded in each year since 1887 :—

1887	... ...	455,261	1891	... ..	513,132	1895	... ...	538,540
1888	... ...	468,039	1892	... ...	611,742	1896	... ...	596,472
1889	... ...	518,562	1893	... ...	511,831	1897	... ...	749,916
1890	... ...	463,616	1894	... ...	607,179			

Of the total deaths registered, 396,154 occurred among males and 353,762 among females, against 312,458 and 284,014, respectively, in 1896.

The computed death-rate per 1,000 of population in 1897 was 39·84 against 31·69 in 1896 and a decennial mean of 29·53. The millesimal rates of males dying to males living was 40·68, and of females dying to females living was 38·95. In 1896 these ratios were respectively 32·09 and 31·27. For every 100 females who died 111·98 deaths among males were recorded, but these proportions vary considerably in the following collectorates :—

In Khándesh the ratio of male to female deaths was			113·37 per cent.
„ Násik	do.	do.	118·86 „
„ Thána	do.	do.	113·53 „
„ Bombay	do.	do.	133·74 „
„ Kolába	do.	do.	113·68 „
„ Ahmednagar	do.	do.	114·36 „
„ Sholápur	do.	do.	113·55 „
„ Kánara	do.	do.	112·83 „
„ Kaira	do.	do.	121·98 „
„ Panch Maháls	do.	do.	119·95 „
„ Karáchi	do.	do.	122·30 „
„ Hyderabad	do.	do.	124·35 „
„ Thar and Párkar	do.	do.	116·75 „

The recorded death-rates per 1,000 of population were higher than in 1896 in all the collectorates and districts, except in the collectorates of Broach, Kaira, Panch Maháls, Ahmedabad, and Hyderabad and the district of Thar and Párkar. The recorded death-rate per 1,000 of population was higher than the annual mean of the preceding ten years in all districts except the collectorates of Broach, Kaira, Panch Maháls, Ahmedabad, and Hyderabad.

Deaths by sexes.—In the City of Bombay, Shikárpur, Upper Sind Frontier and Thar and Párkar the recorded death-rates of females were higher than those among males. In Broach and Karáchi the death-rates of males and females were about equal. In the remaining collectorates the death-rates of males exceeded those of females. In 1896 the females death-rates exceeded those among males in the City of Bombay, Thána, Karáchi, and Upper Sind Frontier.

Deaths by ages.—Taking the ages at the time of death, there was an increase in the ratio per 1,000 of population at every age period as compared with last year, and as usual the infantile mortality was very high. In times of famine and distress it is the people at the extremes of life who succumb, and this is exemplified in the present case, as the largest increase in the death-ratios per 1,000 of population was in the case of "infants under 1 year" and people of "60 years of age and upwards." Taking the percentage on total deaths under one year, the percentage is 18·19 against 20·46 in 1896 and 22·30 in 1895. Under 5 years of age the percentage is 36·33 as compared with 40·49 last year, and in old people of 60 and upwards the percentage is 14·57 as against 13·57 last year and 14·81 the year before. The period of greatest immunity was, as in the past two years, in the age period of above ten and under fifteen. The deaths this year have been more evenly distributed amongst the age periods, the percentage on total deaths amongst children under 5 years of age being over 4 per cent. less, in the age period "60 and upwards" 1 per cent. more, and the remaining increase being divided amongst the other age periods.

Deaths by caste or class.—According to the Census of 1891, the Mahomedan population numbered 3,501,910 persons, amongst whom, in 1897, 105,548 deaths were recorded against 85,746 in 1896, the death-rate being 30·14 per 1,000 of population against 24·48 in 1896. The Hindu population amounted to 14,897,629 persons, amongst whom 635,114 deaths or 42·64 per 1,000 of population were registered. In 1896 the total deaths amongst this race were 502,590, equal to a death-rate of 33·74 per 1,000 of population. Amongst the Christian population, numbering 122,089 persons, 4,608 deaths were reported during the year against 3,016 in 1896, the death-rate being 37·74 against 24·70 in 1896. The Pársi population amounted to 73,945 persons,

amongst whom 2,408 deaths, or 32·56 per 1,000 of population were recorded. Under the heading "Other Castes" are included all those not belonging to either of the above sects, who, by the census of 1891, numbered 224,773 persons, amongst whom there were 2,238 deaths or 9·95 per 1,000 of population recorded during the year 1897. Among Mahomedans the maximum death-rate during the year (72·95 per 1,000) took place in the City of Bombay, and the minimum (14·13) in Hyderabad. In 1896 the maximum death-rate was 53·08 in the City of Bombay, and the minimum 16·04 in Hyderabad. Among Hindus the maximum death-rate (57·44 per 1,000) was in the City of Bombay and the minimum (21·99) in the collectorate of Panch Maháls. In 1896 these rates were Násik (44·77), and Thár and Párkar (23·53) respectively.

Deaths by causes.—The subjoined table shows the deaths in 1897, arranged according to the specified causes laid down by the Government of India, and contrasted with the results for 1896, and the mean of the preceding ten years. The causes of death will be briefly noticed in the next section :—

Causes of deaths.	Mean for 10 years, 1887–1896.		1896.		1897.	
	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.
Cholera	25,531	1·43	35,404	1·88	57,109	3·03
Small-pox	3,710	0·21	6,443	0·34	3,835	0·20
Fevers	370,325	20·72	412,229	21·90	452,596	24·05
			2,086	**0·11**	**46,944**	**2·49**
Dysentery and diarrhœa ...	38,449	2·15	36,046	1·92	85,966	4·57
Injuries	5,894	0·32	6,238	0·33	6,907	0·37
Other causes	84,528	4·73	100,112	5·32	143,503	7·62
All causes	528,437	29·56	596,472	31·69	749,916	39·84
			2,086	**0·11**	**46,944**	**2·49**

N.B.—Figures in thick type denote deaths from plague which have been included under "Fevers."

The recorded death-rates among the urban and rural population of the Presidency were, respectively, 56·73 and 37·49 per 1,000 of population, against 37·21 and 30·92 in 1896. Among the rural population the death-rates were higher than in the urban population in the collectorates of Belgaum, Dhárwár, and Kánara. The difference is most marked in Kánara, where the rural death-rate exceeded the urban by 12·16.

Chief Diseases.

Cholera.—In the year 1897 there were 57,109 deaths recorded as due to cholera compared with 35,404 deaths from the same cause in 1896. The province of Sind was free from the disease, the Gujarát district suffered but slightly, and the collectorate of Kánara was lightly affected. The Deccan districts, in which famine prevailed, suffered most.

In December 1896, 911 deaths were reported from nine districts. These districts were Bombay City, Kolába, Ahmednagar, Sholápur, Sátára, Belgaum, Dhárwár, Bijápur and Kánara. In January cholera had ceased in Bombay City, Kolába and Ahmednagar, but continued in the other districts, Ratnágiri being affected in addition. There were 1,225 deaths reported in seven collectorates. During February and March the same collectorates continued to be affected, the mortality diminishing in February but rising again in March. In April the same districts reported deaths, and in addition Bombay City was affected. In May, in addition to the above, the Kolába, Poona, Surat and Broach districts returned cases, and the mortality in the Sátára District was especially heavy and the spread was in a great measure due to workers on famine relief camps dispersing when any outbreak occurred, and thus spreading the disease and also falling victims themselves, as by not continuing on the works they did not get the famine relief. In the Belgaum and Bijápur districts also, both famine affected areas, the mortality was especially heavy. As regards Surat, Broach and the other Gujarát collectorates the mortality was slight, and also after May the Kánara collectorate was so slightly affected that they need not be further considered.

In June all the Deccan and Konkan districts were affected and continued to be so to November; the famine affected districts of Násik, Poona, Sátára and Belgaum suffered severely in June. In July the highest number of deaths from this disease were returned. The districts of Ahmednagar, Poona, Sholápur and Sátára were chiefly attacked, the collectorate of Poona showing a high mortality. In this district all famine camps but two were closed on account of the rains, and no doubt the people living in their own homes and not on well-ordered famine camps, receiving regular though small payments, fell off in condition and were rendered more liable to suffer from this and other bowel diseases. Matters began to mend in August, improved month by month as the year closed, so much so that, at the close of the year, for the month of December only 121 deaths from eight circles were reported.

By seasons: 37,054 deaths occurred in the rainy season of 122 days; 14,060 in the hot and dry season of 61 days; 4,083 in the cold season of 121 days; and 1,912 in the hot and damp season of 61 days.

Out of 220 rural circles 138 were affected by cholera during the year. Out of 56 town circles 41 were affected: and out of 20,545 villages in the districts affected by cholera, 3,456 or 16·82 per cent. were attacked during the year. The highest percentage (41·95) took place in the Poona collectorate, where out of 1,187 villages 498 were affected. In Sátára, Belgaum, Sholápur, Bijápur and Ahmednagar collectorates the percentages were 38·87, 37·69, 33·38, 31·71 and 16·13 respectively, and in the remaining collectorates the percentages were below 15 per cent.

Small-pox.—During 1897 there were 3,835 deaths from small-pox (2,005 males and 1,830 females) against 6,443 in 1896 and a decennial mean of 3,710. There is an increase in the number of deaths in the Central and Sind registration districts, but on the total number the deaths are less this year by 2,608, and the ratio per 1,000 of population is 0·20 this year as against 0·34 last year, and 0·21 the decennial mean. The decrease is most marked in the Western and Gujarát circles. As regard collectorates, there is an increase in Ahmednagar, Poona and Sholápur in the Central Registration District, Dhárwár and Bijápur in the Southern, Broach in the Gujarát, and Karáchi, Thar and Párkar and Upper Sind Frontier in the Sind Registration District. The highest death ratios occurred in Broach 1·13 and Thar and Párkar 1·01, and the lowest 0·01 in the Ratnágiri and Kaira districts. According to age 29·46 per cent. of the small-pox deaths occurred amongst infants under one year of age, whilst 46·39 per cent. took place among children over 1 and under 12, the remaining 24·15 being among persons over 12 years of age.

Fever.—During 1897, 241,140 males and 211,456 females, or a total of 452,596 persons were reported to have died from fever against 412,229 in 1896, showing an increase of 40,367 deaths for the year, the mean for the previous ten years being 370,325. In the Western Registration District fever caused a high mortality—28·66 per 1,000 during the year against 24·08 in 1896 and the decennial mean 20·70. The increase is chiefly due to the prevalence of plague in Bombay, and it is quite clear that many plague deaths escaped registration as plague deaths and were put down to other causes. In the Central Registration District the death ratio was 25·28 against 21·40 in the previous year and 20·27 the ten years' mean. If the number of deaths registered as due to plague is deducted from the deaths due to fever, the fever deaths would be less than last year. In the Gujarát Registration district the ratio for the year was 22·73 against 29·42 in the previous year and 28·55 the decennial mean—less than the previous year's ratio and the ten years' mean, in spite of a heavy outburst of plague in the Surat district. In the Sind and Southern Registration Districts the respective ratios for the year were 21·16 and 19·60 against 19·34 and 14·87 in the previous year, and 18·13 and 16·57, the ten years' mean. With the exception of the Town and Island of Bombay, the collectorate of Poona heads the list with a high ratio of 32·22 against 22·16 in 1896 and 20·73 in the previous ten years; and the lowest ratio 13·54 was attained in the Hyderabad collectorate, the Presidency rate being 24·05 against 21·90 in the previous year and 20·72 the decennial mean.

Although famine was present, yet owing to the scanty rainfall in the latter part of the monsoon of 1896, the deaths from fever would in all districts except the Southern and Western Registration Districts have been about equal to the numbers reported last year. In the Gujarát Registration District the death ratio per 1000 would have been lower than for many years past. I am unable to account for the increase in the Southern Registration

District: the increase in the Western Registration District is, I think, due to deaths from plague being entered as due to fever, as the fever deaths (excluding deaths returned from plague) in Bombay City are abnormally high.

In spite of the plague the fever mortality, which was noted as low in the last three months of the year 1896, continued below the figures of the corresponding months of the previous year up to the end of May 1897, but exceeded the ten-year mean. In June the lowest fever mortality for the year is as usual reported, though it is higher than that for the corresponding month of the previous year and the corresponding decennial period. After June a rise takes place, and the maximum mortality is reported in August and continues high till the end of the year.

In accordance with the desire of the Army Sanitary Commission a slight meteorological sketch for the year is appended. There was no rain for the first three months of the year. Very light showers fell in April and May except in the Belgaum district, but in June the monsoon began, and fell throughout the country in a very favourable way. The maximum temperature diminished with the rainfall, and also did the range, but increased again when the rain ceased. The price of food-grains seriously increased, and the maximum price was reached in August, but favourable rains in September caused a fall.

Dysentery and Diarrhœa.—During 1897, dysentery and diarrhœa caused the deaths of 46,309 males and 39,657 females, or a total of 85,966 persons against 36,046 in 1896 and a decennial mean of 38,449—an increase of 49,920 over last year and of 47,517 over the decennial mean. The Central Registration District heads the list with a ratio of 8·53 per 1,000 against 2·70 in 1896 and 2·30, the decennial mean. The Western Registration District comes next with a ratio of 5·49, the Southern Registration District 4·84, the Sind Registration District 0·37, and the Gujarát Registration District 0·35. In the Presidency the rate was 4·57 against 1·92 in the previous year and a decennial mean of 2·15. All the collectorates excepting Panch Maháls and Ahmedabad show higher rates than in the previous year. High ratios were recorded in Sholápur 12·22, Poona 9·70 Násik 9·32, Sátára 8·22, Ahmednagar 7·76, Bijápur 6·47, Belgaum 6·38, Kolába 6·04, Ratnágiri 5·85, and Khándesh 5·29; and the lowest 0·07 in Panch Maháls and 0·06 in the Upper Sind Frontier. There is no doubt that the large rise in mortality from dysentery and diarrhœa is due to famine. In areas where the famine most prevailed, the mortality is seen to be the highest, and those areas upon the fringe of the famine, such as Thána, Kolába, Ratnágiri, Dhárwár and Kánara, the death-rate is also high. The increase in the Gujarát Registration District, which was unaffected by famine, is slight. In Sind, in which the number of deaths was more than double that of the preceding year and the death-rate was more than twice that of the decennial mean, there was, the Deputy Sanitary Commissioner Sind Registration District reports, "comparative dearness of "provisions in the province."

Injuries.—During 1897, 3,993 males and 2,914 females or a total of 6,907 persons met with violent deaths. The mortality from these causes is more by 669 than that reported in 1896, when 6,238 deaths were recorded. Of these deaths 3,016 occurred from drowning, 1,221 resulted from snake-bites, 663 from wounds, 198 from hanging, 94 from poisoning, 97 from attacks by wild beasts, and 1,618 from causes not specified.

Other Causes.—The recorded deaths from causes other than those specified number 143,503, of which 72,265 occurred among males and 71,238 among females. The total for 1896 was 100,112, so there is an increase of 43,391. Under this heading all deaths are included which cannot be classed under cholera, small-pox, fever, dysentery and diarrhœa, and injuries. The number under this heading may be expected to increase as more accuracy in entering the causes of deaths is attained, but in the year under report the prevalence of famine and plague has no doubt led to the large increase under this heading.

Sanitary Works.

All available information under these sections has been thrown in a tabular form, and will be found in Appendices IV. and V.*

---

* Not reprinted.

There were 167 Municipalities in the mofussil with a population of 2,232,737 souls and an income of Rs. 58,92,572. Out of this income, Rs. 33,71,008 or 57·21 were allotted for sanitary works, and out of this allotment Rs. 28,60,607 or 84·84 per cent. were spent. Out of the total expenditure, Rs. 14,77,597 or 51·65 per cent. were spent on conservancy, Rs. 9,07,896 or 31·74 per cent. were spent on improvement of water-supply, Rs. 1,71,085 or 5·98 per cent. on improvement of town sites, Rs. 51,658 or 1·81 per cent. were spent on construction and repairs of markets and slaughter-houses, Rs. 14,034 or 0·49 per cent. were spent on sanitary arrangements during fairs and festivals, and Rs. 2,38,337 or 8·33 per cent. were spent on other sanitary objects, including construction and repairs of tanks, &c.

The Bombay Village Sanitation Act of 1889 under the conditions laid down in Government Circular No. 45, dated 5th January 1895, and under a modified form sanctioned in Government Resolution No. 1090, dated 6th March 1896, has been introduced in 62 other villages during the year 1897, making a total of 282 since the introduction of the Act. In 38 of the 62 villages of the Poona Collectorate the requisite notifications were issued under Part II of the Village Sanitation Act in 1897, and eventually confirmed, but the Act has not yet been formally introduced.

Personal Proceedings and General Remarks.

The plague and famine, which had visited the Presidency in the latter half of the year 1896, continued on in 1897, and great suffering and a high death-rate has resulted. The plague continued throughout the year, but owing to the timely rainfall, especially in September, the cultivators were encouraged to return to till their fields, and the famine works closed, except in three places.

The touring during the year was chiefly for famine purposes, but visits of inspection for selection of sites of plague hospitals and camps were also made. The districts of Sátára, Poona, Ahmednagar, Násik, Khándesh and Thána were visited.

Throughout the presidency, owing to the plague, much more attention is being devoted to the sanitation of towns and villages, and so far this is beneficial; but in the larger towns, works of a more permanent sanitary character will have to be undertaken if sanitary improvement is to be kept up. One such useful measure for Bombay is now under consideration—a scheme to open out Bombay and provide it with wide streets and sanitary dwellings under the guidance and control of a Building Trust. It is to be hoped that on the Board of Trustees a medical officer will be appointed to enforce his views in the proper sanitary building of houses and chawls, and that advice on such important points shall not be gathered here and there from various Medical and Sanitary authorities by the different members of the Trust. Another town, which will certainly need attention in the way of abolishing insanitary houses and providing proper water-supply and sewerage, is Poona. At present the town, though clean, pours the contents of its cesspools into one of the streams running through it, and this is banked up by the water of the Mutha River, and a foul, almost stagnant, stream results. For large towns with an adequate water-supply nothing but a well-devised sewerage scheme is suitable. The incessant watchfulness necessary when cesspools, &c., are cleared out by hand will never be maintained in a Native town, by Native agency.

Plague.

A brief sketch of the course of the plague during the year is given.

Particulars are not entered into, as these may be obtained from the exhaustive reports (noted below) which have been written by the various officers employed in plague operations and published by Government or Local authority.

1. Account of Plague Administration in the Bombay Presidency.
2. Supplement to above.
3. Report on the outbreak of Bubonic Plague by the Municipal Commissioner.
4. Report on the Bubonic Plague in Bombay by the Chairman, Plague Committee.
5. Report on the Plague in Karáchi under the Plague Committee.
6. History of the Plague in Sind by the Acting Commissioner in Sind.
7. Report by the Collector, Karáchi.

8. Report on the outbreak of Bubonic Plague in the City of Karáchi by the Medical Officer of Health.
9. Investigation on Plague by Mr. E. H. Hankin.
10. Joint report on the Epidemic of Plague in Lower Damaun.

Great power and assistance was given to all authorities by the passing of the Epidemic Diseases Act, III of 1897, on 4th February 1897, which conferred very large powers.

The general course pursued was, as regards preventive measures, to hinder those coming from an infected area from entering a healthy town or village, by detention at an observation camp till freedom from infection was assured and the person and personal effects disinfected.

When the disease was apprehended, or had appeared in a town, usually a small committee with full powers supervised the whole proceedings. Otherwise in a district the Collector managed the business. In large towns a committee is preferable, provided it is not too large. The town was divided into wards and a Superintendent in charge of each, with suitable assistance, which comprised a searching staff, a medical staff and a cleansing staff.

The searchers, under carefully framed rules, visited the houses, and if any sick were found, the medical staff were called in to diagnose the case, which, if considered plague, was removed to hospital and the other inmates to a segregation camp to be disinfected and remain there for 8 or 10 days. The cleansing staff then cleaned and disinfected the infected building. In some instances in large towns, instead of searching daily, the Superintendent watched the daily number of deaths, and kept a list of the sick, any suspected case being examined. If the number of deaths mounted up, the ward was searched, and if it could be done, the people turned out into camp.

As a rule all the houses were cleaned and opened up either by the staff or the owners, and sanitation strictly adhered to. All deaths had to be reported, and if the cause of death was not clear, a medical inspection was made. In large towns every now and again, without warning to the people, the whole searching staff was concentrated on a given ward, a cordon having been put round to prevent ingress or egress, and the whole place rapidly and thoroughly searched with a minimum of inconvenience to the inhabitants, and this was very useful in those cases in which wards had become seriously infected. Another good measure, though it could not always be done, was to turn the whole ward out into a camp outside whilst the houses were cleaned and opened up to light and air.

In addition, at various points on the railway, inspection stations were organised and travellers examined, and according to the rules in force either those who were sick were only detained, or all travellers were detained for a fixed period, disinfection of the person and effects being also carried out.

Of the twenty-four circles including Bombay the plague had not appeared at the end of 1896 in the districts of Násik, Sátára, Ratnágiri, Belgaum, Dhárwár, Bijápur, Kánara, Panch Maháls, Thar and Párkar and Jacobabad. Local or indigenous cases had been reported in Bombay City, Ahmedabad, Karáchi, Bándra and Bhiwndi towns and in one village of the Kolába Collectorate. In Ahmedabad Town the local cases (2 in number) were reported at the very beginning of the outbreak there, but the rest were imported. Imported cases only had been reported as occurring in the collectorates of Khándesh, Ahmednagar, Poona, Sholápur, Surat, Broach, Kaira, Hyderabad and Shikárpur.

In January, cases occurred in the districts of Násik, Sátára, Ratnágiri and Belgaum. In February a case occurred in the Thar and Párkar District, and in March 2 cases in the Jacobabad Circle.

The first case reported in the Dhárwar District was in October and in the Bijápur District in November. The districts of Kánara and the Panch Maháls alone returned no cases of plague during the year, and the districts of Khándesh, Ratnágiri, Dhárwár, Bijápur, Broach, Kaira, Thar and Párkar and Jacobabad were but lightly visited.

At the end of 1896 there had been a total of 2,908 attacks and 2,086 deaths, and the following table gives the progress of the disease by months in each of the 24 circles.

No.	District.	Total for 1896.		January.		February.		March.		April.		May.		June.		July.		August.		September.		October.		November.		December.		Total for 1897.		Grand Total from September 1896 to 31st December 1897.

The figures shown are from returns received in this office and do not tally with returns elsewhere published. In the general returns the deaths are included under the heading "Fever."

Khándesh.—The plague was kept out of this district, only imported cases being reported (most of which were detected at the railway inspections) up to December, when Jalgaon town was infected. There were 109 attacks and 81 deaths in 11 villages.

Násik.—The outbreak began in January, but was very slight, and the numbers of cases and deaths declined till in May and June there were practically none. In July, however, the district was again re-infected and during the latter half of the year there was a serious outbreak; altogether 60 villages were affected and 1,389 attacks and 1,075 deaths reported.

At one village the opposition to plague measures led to the villagers assaulting the medical men and others coming to the village to prosecute plague measures.

Thána.—Up to the end of December 1896 thirteen towns or villages had reported cases which were all imported cases except in the towns of Bándra and Bhiwndi, which had become infected. The imported cases numbered 22, the local cases 107, total 129, and there had been 95 deaths. After the beginning of the year 1897 the attacks and deaths increased very rapidly, attaining the maximum in the month of March and then declining till a minimum was reached in the month of August, after which there was an increase, but kept within narrow limits till the close of the year. Besides the 13 villages in 1896 there were 83 other villages infected in 1897.

An interesting account of the plague in this district by the Collector, Mr. Logan, I.C.S., appears on page 191 of the Bombay Presidency Report, in which he quotes from the reports furnished by Surgeon-Major A. V. Anderson, Deputy Sanitary Commissioner, Western Registration District, and Assistant Surgeon R. R. Dadina, the Medical Officer of Kalyán town and the Vice-President of its Municipality. Very rightly is the work of Assistant Surgeon Dadina praised, and it shows how in a crowded and dirty town vigorous measures of inspection, segregation and disinfection can keep the disease down.

Bombay City.—Long and admirable reports have been written on the outbreak in this city and the measures taken to minimise the outbreak, by the Municipal Health Officer, the Chairman, Plague Committee, and the Health Officer of the Port of Bombay. By the close of 1896, 2,542 attacks and 1,803 deaths had occurred. In spite of great zeal and energy in cleansing and searching out cases on the part of the Municipal Executive, the mortality from the disease continued to rise, there being no rigid enforcement of isolation and segregation measures, and attained its highest maximum in the week ending 16th February 1897, on which date the total mortality for the week stood at 1,710, of which the reported plague deaths were returned at 845. At the end of the previous week the total mortality was 1,891 with 745 reported plague deaths. After the 16th February the mortality from all causes began to decline. By the end of February a Plague Committee was constituted which began work by appointing a Secretary on the 2nd March and setting to work by building hospitals, searching, isolating, and segregating. The fall after the 16th continued, and the total mortality for the week ending 29th June was 517, of which the reported plague deaths were 11. In fact, in the month of June the total mortality was 2,163, whilst the attacks and deaths from plague were returned at 186 and 99 respectively. In July there was a further fall, and 62 attacks and 44 deaths from plague were returned, but the total mortality for the month was higher, after which a recrudescence began and a second and severe outbreak took place, the total attacks and deaths for the year 1897 being returned as 11,967 and 10,237.

To prevent cases of plague being carried by sea or being imported, a system of medical inspection of ships, their crews and passengers was organised and successfully worked by Surgeons-Major MacCartie, C.I.E., and Crimmin, V.C., a full report of which is in the account of plague in the Bombay Presidency.

Kolába.—The district was not severely affected; the cases, as a rule, occurring at coast towns or villages easily reached from the sea-board and being introduced from Bombay. The outbreak began in January (imported cases being detected early in October) and reached its maximum severity in April. The total numbers are not large, but to combat it strained to the utmost the zeal and energy of the authorities. The total numbers reported are 1,531 attacks and 1,322 deaths.

Ahmednagar.—With the exception of local cases the disease did not show itself in this district till September, when an outbreak began, increasing in severity to the close of the

year, but the total attacks were 557 and deaths 390. The high death-rate shown by this district is due to the effects of famine.

Poona.—In this collectorate only the chief town had become infected by the end of the previous year and in this town the vigorous measures organised by a Committee under the late Mr. Rand, I.C.S., brought down the death-rate and almost freed the town from the plague in June, but a recrudescence or re-infection took place, and in July a rise in the attacks and deaths took place leading to another serious outbreak. In the whole collectorate 119 towns and villages were affected, and there were 12,024 attacks and 8,910 deaths.

Sholápur.—The plague was kept out of this district till September, after which a sharp outbreak commencing in Sholápur town took place, and continued increasing in severity up to the close of the year. 69 villages were infected during the year and there were 2,846 attacks and 2,353 deaths. This was a famine-affected district, but fortunately the famine had closed when the serious outbreak began. I understand that many of the inhabitants got out of Sholápur town at the first indication of a serious spread of the disease and thus infected other villages.

Sátára.—This collectorate escaped lightly up to the end of June, but there were a good many people who returned to their homes from Bombay and probably also from the Poona District, and the serious outbreak began in Karád town and from there the infection spread, especially up the eastern side of the collectorate. 194 towns and villages were infected and there were 13,242 attacks and 10,031 deaths reported.

Ratnágiri.—This district was very lightly affected. There were 27 attacks and 26 deaths in 10 villages—all near or upon the coast.

Belgaum.—With the exception of two imported cases early in the year, this collectorate escaped till October, when an outbreak commenced affecting 6 towns and villages, in which 569 attacks and 444 deaths occurred.

The districts of Dhárwár and Bijápur were lightly affected, and Kánara not at all.

The report on the outbreak and progress of plague in the Province of Sind by Surgeon-Captain H. C. L. Arnim, D.P.H., Deputy Sanitary Commissioner, Sind Registration District, is appended :—

" As pointed out in the Deputy Sanitary Commissioner's report for the year 1896, plague was first detected in Karáchi City early in the month of December. Up to the termination of the year 1896, 63 cases and 59 deaths from plague have been reported. These cases were all of local origin ; the most careful enquiries having failed to discover the original case or cases importing the disease. At this period the remainder of the Sind Province with the exception of Kandiáro and Shikárpur, into which towns cases had been imported, was free from the disease.

" 2. During the year 1897, plague gradually spread along the main lines of communication ; and it was not until 16th August 1897 that Sind was declared to be entirely free from the disease. During this period, 6,057 cases and 4,770 deaths had been reported in the province.

" 3. Among these figures, those resulting from a second and localized outbreak in Kotri town (the first case of which was reported on October 28th) have been omitted. The details of this outbreak will be referred to later.

" 4. In this report it is intended to refer to the disease as it appeared in 5 districts into which the province is divided. In the case of the Karáchi District, the statistics referring to the Karáchi Town Circle have been prepared separately from those of the remaining portion of the district.

" 5. *Karáchi Town Circle.*—As stated above, the disease was present in the town of Karáchi at the commencement of the year under report, and it was not until 27th July 1897 that the epidemic was finally stamped out there. During this period, 4,180 cases and 3,396 deaths were reported in the circle.

To repeat : plague first appeared in the Karáchi Town Circle on December 10th 1896, the last case being reported on July 27th 1897. During this period, 4,180 cases and 3,396 deaths were reported. Of these cases all, excepting 15 cases imported, were of local origin.

" 6. *Karáchi District excluding Karáchi Town Circle.*—As before stated, at the end of the year 1896, plague was reported from no other part of this district, excepting in Karáchi town.

" During the year 1897 plague was reported from 9 of the rural circles of the Karáchi District. In all, 231 cases and 169 deaths occurred. Of the cases, 188 were imported ones, and 43 were reported as of local origin. In these rural circles no less than 46 towns and villages were affected ; but only from 4 places were local cases reported, the others reporting only imported cases.

" The last case reported from the Karáchi District (excluding Karáchi Town) was on 26th May 1897.

" It is regretted that details are not available, in the office, for the preparation of mofussil tables, showing cases and deaths by castes and age periods.

" 7. *Hyderabad District.*—In this district, a case (an imported one) had been reported from the Kandiáro Circle on December 27th 1896.

" During the year 1897, plague was reported from 9 rural and urban circles in the Hyderabad District. In all, 644 cases and 500 deaths occurred. Of these cases 80 were reported as imported, and 564 were of local origin. No less than 23 towns and villages were affected ; but from only 3 places were local cases reported, the others reporting only imported cases.

" The last case reported from the Hyderabad District was on 2nd June 1897.

" No data are available for the preparation of caste and age tables for this district.

" 8. *Shikárpur District.*—An imported case was reported from Shikárpur Town on December 30th 1896. This is the date of the first appearance of the disease in Shikárpur District.

" During the year 1897, plague was reported from 10 rural and urban circles in this district.

" Altogether 996 cases and 700 deaths occurred, of which cases 115 were imported and 881 of local origin. Forty-two towns and villages were affected ; local cases being reported from 24 places, the others reporting only imported cases.

" The circles have been mentioned in the order in which the disease first appeared in them.

" The last case reported from the Shikárpur District was on June 24th 1897.

" No data are available for the preparation of caste and age tables.

" 9. *Thar and Párkar District.*—In this district the disease was reported from only one circle, Mirpur Khás. Between the dates of 15th February and 27th March 1897 three cases, all imported ones, were reported from the town of Mirpur Khás. Two of the cases were fatal. The disease was reported from no other part of this district.

" 10. *Upper Sind Frontier District.*—Here three cases were reported from one circle (Jacobabad) between the dates of 13th March and 6th April 1897. Two cases were imported, the third being reported as of local origin. All three cases were fatal. The disease was not reported from any other part of this district.

" 11. Regarding the second outbreak of plague reported from Kotri town referred to in paragraph 3 of this report. The first case was reported on 28th October 1897 (the town having been free from plague since). The origin of the outbreak was stated to be unknown. But it is probable that the disease was re-imported into the town from an infected area outside the province.

" Up to the end of the year, 93 cases and 64 deaths were reported from this town. All were of local origin.

" 12. During the whole period of the epidemic the Deputy Sanitary Commissioner was ordered to remain at Karáchi, to advise the local authorities as to the measures to be adopted in dealing with the local outbreak, the incidence of the disease being far heavier in Karáchi than in any other part of the province.

" On 12th December 1896, the Karáchi Municipal Health Officer had shown some suspicious cases to the Deputy Sanitary Commissioner, which cases the latter diagnosed to be plague. The Deputy Sanitary Commissioner took immediate steps to acquaint the Local Medical and Revenue authorities of the presence of the disease in the city, and also wrote to the Municipality regarding the measures which he considered should be adopted under the circumstances. A report was also made to the Sanitary Commissioner with Government, and copies forwarded to the Local Revenue Officers. Later on (4th February 1897) the Deputy Sanitary Commissioner was placed in special medical and sanitary charge of the Sadar Bazár, and powers under the Epidemic Diseases Act granted to him ; to these duties were added (in February 1897) those of the medical and sanitary supervision of the suburban areas (those portions of the Municipal area without the old Native City). Finally (on 20th March 1897) the Deputy Sanitary Commissioner was appointed medical member of the Karáchi Plague Committee.

" 13. A few words may be added as to the earlier steps taken by the Deputy Sanitary Commissioner with a view to check and control the spread of epidemic diseases in the province.

" It is one of the recognised duties of the Sanitary Officer to be prepared with measures to combat, *on its earliest incidence*, any epidemic outbreak which may appear within his district. In reference to this duty, it is in the first instance necessary to consider the legal powers which exist for the carrying out of the measures to be recommended. Without legal authority for enforcing their application, sanitary recommendations are useless. When it is seen that existing legal powers are not sufficient for the rapid application of emergent measures, it becomes clearly the duty of the Sanitary Officer to point out the deficiency to the proper authorities.

" 14. In the correspondence ending with his letter No. 932, dated 26th June 1896, the Deputy Sanitary Commissioner had pointed out the deficiencies in the Bombay District Municipal Act with regard to the existing powers for dealing with emergent epidemic outbreaks ; and had suggested amendments and additions. In his letter No. 959, dated 3rd July 1896, the Deputy Sanitary Commissioner had pointed out the dangerous manner in which infectious disease was spread from town to town and from village to village in the province, and had suggested remedies for the future prevention of the spread of disease by these channels.

" In his letter No. 1243, dated 18th August 1894, the Deputy Sanitary Commissioner had also suggested simple measures for preventing the spread of infectious diseases by river craft. The Sanitary Department in Sind had not been behind hand in pointing out the most urgent deficiencies in the existing laws and regulations for dealing with emergent epidemic outbreaks, and in suggesting measures for their reconstruction and amplification.

" Had powers existed, on the first appearance of plague in the province, to deal with the earlier cases in accordance with recognised methods, there is not the slightest doubt that incalculable saving in life and property would have resulted."

The disease is spread chiefly through human intercourse. In noting the beginning of the various local outbreaks, there is nearly always some history of importation from an infected area, and the maps attached to reports show how the disease spread along the lines of railway and extended to ports served by coasting steamers and vessels. It appears to me clear that human intercourse is the great factor in the spread of the disease—not of course by the human being alone, but also by means of his clothing and the personal effects he carries from one place to another, and hence the necessity of disinfecting not only the person of a traveller from an infected area but also his personal effects. Rats are also the carriers of the disease. Instinct warns them to migrate, and those infected travel as far as they can, infecting others, and those arriving at their destination spread the disease in houses. There is an interesting note on this subject by Surgeon-Major Anderson, Deputy Sanitary Commissioner, Western Registration District, on observations made by him in the Thána District and also by Surgeon-Captain T. E. Dyson, Deputy Sanitary Commissioner, Gujarát Registration District, in his report on the outbreak in Bulsár. A certain time elapses before the infection gets a firm hold of the town or village, as indicated by the death-rate after the first probable infection from without. It of course varies and is by no means well-defined, but it would appear to be at least a month ; the period, however, appears much shorter when rats introduce the disease. Once the infection is in a town it seems to cling to houses ; probably it is the floor constantly poisoned by emanations from the sick and rats. The prompt evacuation of an infected quarter, sending people to a camp, and opening up houses, has almost always been followed by good results.

As a detailed account of plague in its medical aspect will be written by the Surgeon-General, only brief general observations are inserted here.

The period of incubation may be from two to ten days. It is generally five days. Cases have occurred where the period of incubation appeared to have extended over ten days, but in some cases this was probably due to opening bundles of personal clothing of a previous case which had not been disinfected.

Males are attacked more frequently than females, but the death-rate amongst females is high. Pregnant women attacked, abort and die. The majority of those attacked are between 20 and 40 years age, but no period of life is exempt.

The plague with buboes is the most frequent. The pneumonic form of plague, though more difficult to diagnose, is the more fatal. The great majority of buboes occur in the lower half of the body, but whether in the upper or lower region they are most frequent on the right side.

The mortality is very high—over 60 per cent. of those attacked die, but when at hospitals the cases dying within 24 hours after admission are eliminated the death is below 50 per cent.

Cases have occurred in which the same individual has had a second attack after an interval, but these cases are few.

The preventive inoculation introduced by Mr. Haffkine, C.I.E., must not be unnoticed. Accounts of the procedure have already appeared. I have little doubt but that the inoculation is efficient, but for how long the effect remains there is not as yet sufficient evidence to show, nor as regards the after-effects; but no evidence has been forthcoming to show that any serious permanent after-effects have been induced.

Report of the Sanitary Board for 1897.

Preliminary.—The year under report does not show any great progress in sanitary works. Owing to the special measures taken by Government, due to the plague, the ordinary sanitation of towns and villages has been very much better looked after, and the general state of cleanliness is probably better than it has ever been, and the Board hopes that this state of things may continue after the plague has passed away; but, unless municipalities are dealt liberally with as regards plague expenditure, many projects will be delayed indefinitely for want of funds.

Shikárpur.—The municipality have shelved the proposal to carry out a small water-supply scheme, preferring to continue relying on wells sunk in a sub-soil saturated with centuries of sewage, and they are allowing more private wells to be sunk in the town each year; in most cases these are sunk in the ground floor of the houses themselves, or in a small enclosure where cattle are kept. Many of the streets have been paved with bricks, and a considerable length of side gutters has been made, to carry off the waste water from the numerous wells to the outside of the crowded town. As they insist on these wells, these gutters are decidedly beneficial as far as they go, and every well ought to have a connection with them. The waste water and sullage is at present collected in two large hollows to the west of the town, whence it ought to be pumped, and properly utilised; if all the waste water was taken there, the sullage would be sufficiently diluted for effective use.

The removal of sewage, both liquid and solid, is most primitive and insufficient; and probably not one-tenth part is actually taken outside the town. Many of the side streets are simply latrines, and the supervision is very inefficient. Rubbish is at present filled into a large hollow.

Sukkur.—This municipality has now got a fairly good water-supply, obtained by driving tunnels under the river Indus, through the rock. The first one struck a large spring, which, it was hoped, would give a sufficient supply. A peculiarity of this spring was that the temperature of the water, as it gushed out of the rock, was 12° to 13° *higher* than that of the river water above the tunnel. The discharge of the spring was found to fluctuate to some extent with the height of the river; and in the cold weather, when the river was at its lowest, the spring supply was insufficient. A second tunnel has therefore been driven, and the supply is now believed to be sufficient. The water is pumped by a pair of Worthington engines, to iron tanks on a tower on a small hill, and distributed thence in iron pipes to cisterns and stand-posts.

The special Engineer, lent to the municipality by Government, also worked out an excellent and economical drainage scheme for the municipality, a very necessary measure upon the completion of a water-supply; but the municipality are hesitating, and propose another scheme of surface drainage in connection with their present drains, which ought not to be allowed; as the existing drains are little better than elongated cesspools, which are infecting the subsoil.

Hyderabad.—After years of delay the municipality have at last, under the advice of the Sanitary Board, provided themselves with a pair of Worthington engines for the lift into the storage reservoir in the fort; and have laid down a branch main to supply the cantonment reservoir, instead of having a separate small engine for it. It is extremely probable, from the examination of the dismantled engines, that they would not have stood the strain of the next hot season's work, when the consumption would have increased as usual; but although the terrible results of a breakdown were repeatedly pointed out to them, they only consented at last, after much pressure, to get the new

engines. Much still remains to be done to put their water-supply on an efficient footing. The engines at the river lift, which pump the water into an aqueduct through which it flows into the reservoir whence the fort lift engines raise it into the town, are worn out. One is practically a dummy, as it is unable to lift the water at all when the river is at its lowest ; and the other is now driven much beyond its capacity, and the strain may cause it to break down any day. As the whole supply depends on this lift, the replacement of these engines by an efficient plant is a matter of extreme urgency ; but nothing can be done without money, and the municipality have not yet even raised the loan to pay for the fort engines and cantonment branch, simply because in the present state of the market they find that they have to pay a higher rate of interest than they expected to have to do when the question was considered two years ago. Other very necessary additions to the water-works are :—

(1) Improvements to the settling tanks.
(2) Provision of filter beds.
(3) Covering in the reservoir whence the fort engines pump the water.
(4) Covering in the fort reservoir.
(5) Providing a high-level steel tank in the fort.

The last is very necessary, as the present masonry reservoir in the fort cannot be relied on, owing to bad design and construction, although it has stood hitherto. The municipality have had a drainage scheme drawn out under the instructions of the Sanitary Board, but now talk of shelving it, and extending their inefficient system of surface drains, which are already a nuisance.

Karáchi.—The municipality have completed their drainage scheme for the city, on the Shone system ; great difficulties were experienced, owing to the proximity of the subsoil water ; but the result is a complete success, and house connections are rapidly being made. It only remains to extend the system to the cantonment, which is under contemplation. The sewage is utilised on a farm, which is a remarkable instance of the success, both financially and from a sanitary point of view, of broad irrigation carried out intelligently and under proper supervision.

Karáchi has undoubtedly suffered from an overabundant water-supply, and its unrestricted use has resulted in enormous waste, causing a rise in the subsoil water, and a serious increase of febrile diseases. The municipality has now realised the evil, and are about to charge a rate for the water, which, it is hoped, will check the waste. The large European element in this municipality, and the fact that it has for years had a most efficient and experienced Secretary and Engineer, account for its progressiveness in sanitary matters.

Viramgám.—Nothing has been done here. The boring for an artesian supply, which is much wanted owing to the brackish surface water, has progressed no further. The work is under the Public Works Department.

Ahmedabad.—This municipality is fortunate in having the Honorable Mr. Runchorlál Chotálál as President, whose wonderful energy and foresight, and influence with the people, have enabled him, with the assistance of the Collector, in forcing through both a water-supply and a drainage scheme, against the strong opposition that is invariably experienced when such schemes are first mooted for up-country towns. As usual, however, the people have soon appreciated the benefits, and the use of water has increased to such an extent that a third engine is now being ordered. The drainage scheme has been drawn out by Mr. Baldwin Latham, and a section of one-fifth of the city has been completely sewered, with good results. It is now proposed to carry out the rest of the scheme. The one defect is in the sewage farm, which has been badly managed from the beginning, and is too small. The municipality have, however, recently acquired 300 acres at a further distance of about 3 miles from the city, and propose to lay it out, and manage it, on the scientific principles that have been so successful at Karáchi ; and they are preparing to extend the sewage main to it. It is also hoped that cultivators in the vicinity will buy the sewage.

Dohad.—The Public Works Department carried out the testing of a large well for the water-supply of the town, both for quantity and quality. The results were satisfactory, and the municipality are apparently eager for the supply, but nothing further has been done.

Godhra.—The sanitary state of this town is very defective, and the municipal supervision is very insufficient. A report has been made to the Collector by the Sanitary Engineer.

Dákor.—The sanitary arrangements in this town are not good. A report has been made to the Collector by the Sanitary Engineer. A trial of a well, as a source of water-supply, was a failure, both as regards quantity and quality ; but as there is a large tank near the town, there can be little doubt that proper investigation would procure a good and sufficient supply from the subsoil.

Surat.—The water-works are now, at last, nearly finished; but the extension to Ránder, and some of the distribution arrangements, require completion. The municipality were fortunate in having, in the Public Works Department Executive Engineer, one of the few officers who have made a special study of water-works, and one who has not been discouraged by the procrastination of the municipality, from urging the matter continually. The engines are Worthington's, which raise the water from wells sunk in the river Tápti, into steel tanks on towers, whence it flows into the city. It is remarkable that although the tide affects the level of the river to a point considerably higher up than the head-works, yet it does not affect the quality of the subsoil water obtained from the covered wells sunk in the river bed.

Dhulia.—The water-works have been completed by the Public Works Department, and a drainage scheme is now under consideration.

Jalgaon.—The water-supply project was drawn out by the Executive Engineer a year ago, but was returned for alteration. Nothing further is known about it.

Málegaon.—The Sanitary Board advised on a proposed survey for a water-supply scheme, which has been under discussion for many years. Nothing further is known of it.

Nasik.—The water-works project is still in much the same state as it has been for the last 20 years. A storage tank was begun as a famine work, but very little was done. Strong and continued pressure will be required to make this municipality attend to the urgent sanitary needs of the town, although they are willing to spend a large sum on a bridge for the benefit of the temples on the other bank.

A drainage scheme is an urgent necessity. One masonry drain has been made, which cuts off a certain number of the cesspools from the holy pools where the pilgrims bathe and drink ; but it discharges into an old drain, about half way down the river front, which is practically a cesspool of the worst kind. From the end of this old drain a pipe takes the sewage across the stream, and discharges it into the sandy bed a few feet beyond, whence it flows along a channel in the sand, close to the stream.

Yeola.—The water-works here are being carried out by the Public Works Department, but have come to standstill owing to non-receipt of engines and pipes.

Ahmednagar.—The water-supply for one-third of the town, comprising about the same number of people and at about the same cost as the Yeola scheme, was entrusted to the Sanitary Engineer, and is now finished ; and the trial of the engines is most satisfactory. These are 6 H. P. oil engines, by Clayton and Shuttleworth, and this is the first installation of the kind in India for water-works. The scheme for the rest of the town, on similar lines, has been drawn out ; but it depended on the construction of the Kapurwádi Tank, which was undertaken as a famine work; and as only one-fourth of that work was finished, its completion is a matter that will cause delay to the water-supply scheme.

Poona.—No important sanitary progress of a lasting nature has been made ; but owing to plague, and the special measures taken by Government to suppress it, the town is cleaner than it has been for years. The water-supply and sewerage are matters of extreme urgency, which ought to be faced at once ; and they have been pressed for years. Without a proper water-supply, an efficient sewerage scheme cannot be carried out. That sewerage is a necessity can be seen by visiting the spot where the foul smelling sullage is discharged from carts into a small stream which joins the stretch of water above the Jamsetji Bund ; and this piece of the river is becoming very foul. Even if land for a sewage farm is not available, there are other satisfactory methods of dealing with sewage ; and the town sewage can be, and should be, purified before being discharged into the stream ; and measures to do this should be taken without delay.

Sholápur.—The municipality here are practically depending for their water-supply on one Worthington engine, as their old engine is now incapable of lifting anything like the required supply. The urgent necessity of getting a second Worthington has been

impressed on them for two years, but still they procrastinate. Any accident to their one engine would be disastrous for such a large town.

A survey for a drainage scheme was begun by the Public Works Department, but had to be stopped, as the Overseer was required for the famine. The system of open drains has been carried out here to a large extent, and at heavy cost; and the resulting nuisance, especially from flies and mosquitoes, has at last forced even the municipality to see the necessity of abandoning this system in favour of pipe sewers.

Bársi.—As stated last year, this municipality have seized on *one* unfavourable analysis of a *single* well, to throw up the water-works proposals, and so save themselves from any extra taxation.

Belgaum.—A water-supply project was got up under the supervision of the Board; but is delayed, pending the decision of the Military authorities as to whether they will combine with the town in a joint scheme.

Hubli.—The improvements to the water-supply and drainage, on which the Board have repeatedly advised, have made absolutely no progress. As the town is rapidly growing, something should be done soon.

Gadag.—The Board investigated the question of a water-supply to this rapidly growing town, and advised a preliminary survey; but the Collector appeared to think it inadvisable to have a water-supply without a drainage scheme. This of course is a very correct view; but if always acted on, it would stop sanitary progress in this country altogether. Without a proper water-supply a large town cannot progress; and if funds will not permit (as is invariably the case) of water-supply and drainage being undertaken together, the proper course is to bring in the water first, and deliver it at points where the waste water can be disposed of; and only to extend it generally to the houses when a drainage scheme is carried out.

Akalkot.—This is the chief town of a small Native State, and a water-supply project was got up under the direction of the Board, which, it is hoped, will soon be carried out.

Poona Cantonment.—The Board have advised on certain rules to limit the waste of water in the Sudder Bazár, which waste was a source of increasing sickness. The drainage of the Sudder Bazár is a very urgent matter, and the Board have repeatedly advised its being taken up efficiently. The existing drains are practically elongated cesspools, owing to faulty design and bad gradients; and the stench in the main streets during the hot weather is sickening, even to the natives themselves.

Tirkhundi.—A water-supply project was prepared by the Public Works Department, and returned by the Board, to be recast in accordance with previous instructions.

Awand.—The drainage of the Body Guard Lines has now been re-arranged in accordance with the Board's suggestions.

Sassoon Hospital, Poona.—The drainage of this place is nearly completed, in accordance with the Board's suggestions; but the final testing has not yet been carried out. The Board intend proposing a thorough alteration of the privies and bath rooms of the hospital itself, which are at present very insanitary.

Miscellaneous.—The designs for dispensaries at Ranpur and Hálol, and latrines for various places, were passed by the Board.

Khed.—This town was specially reported on by the Board at the request of Government; and sanitary improvements, suited to the limited funds of the municipality, were suggested.

Government House, Mahábaleshwar.—The Sanitary Engineer advised on the details of the proposed water-supply, and suggested the adoption of a small oil engine plant, as being best suited to the circumstances.

Finally, we would again most urgently draw attention to the remarks in para. 54 of our Report of last year. Owing to plague and famine, it will now be more difficult than ever to get municipalities to carry out sanitary works; and unless some encouragement is given to the very few influential men who take the trouble to interest themselves in such matters, our next year's Report will almost certainly show that progress has fallen off alarmingly.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF THE PORT OF BOMBAY FOR THE YEAR ENDING 31ST DECEMBER 1897.

The following table gives a summary of the shipping and health of the Port of Bombay, and of the work in connection therewith, for the year ending 31st December 1897 :—

Vessels including Native Craft.	Number of Vessels Inspected.	Number of Persons Inspected, including Crew on Vessels.	Number of Vessels Disinfected.	Number of Persons Vaccinated.	Number of Persons rejected or segregated.	Diseases and Number of Cases of Each.					
						Plague.	Cholera.	Small-pox.	Measles.	Scarlatina.	Enteric Fever.
Entered	32,187	602,401	13	111	39,230	79	—	3	3	6	1
Left	40,565	710,716	—	—	3,322	71	—	—	—	—	—
In Harbour during the year ...	56	—	56	50	—	19	30	8	1	3	—
Total	72,808	1,313,117	69	161	42,552	169	30	11	4	9	1
1896	570	112,278	59	777	—	2	38	12	9	3	1

It will be seen from the above table that the numbers of vessels and persons inspected are greater than in 1896. The numbers include every person who left Bombay by sea after 6th February 1897, as well as those who arrived from the ports of Western India between Karáchi and Bhatkal inclusive after 1st April. These wholesale inspections were due to the anxiety of Government to prevent the spread of plague by sea, and were amply justified by the results obtained. The actual numbers of arrivals and departures, including crew and passengers, examined during the period were 1,313,117 souls, and the number of plague cases detected, of which a record has been kept, was 169.

The following table furnishes further particulars regarding vessels which entered the port during the year :—

Year.	Total Number of Steamers and square-rigged Vessels which entered Bombay Harbour from Ports other than Indian Ports.	Number of Passengers.	Total Number of Native Sailing Craft which entered Bombay Harbour from Ports other than Indian Ports.	Number of Passengers.	Total Number of Steamers and square-rigged Vessels which entered Bombay Harbour from Indian Ports.	Number of Passengers.	Total Number of Native Sailing Craft which entered Bombay Harbour from Indian Ports.	Number of Passengers.
a	*b*	*c*	*d*	*e*	*f*	*g*	*h*	*i*
1897	551	27,605	204	191	1,583	289,154	36,831	2,217
1896	684	43,527	235	1,886	1,344	378,553	45,685	Unknown

There is no complete record kept of the crew of incoming vessels, and in the case of native craft none of either crew or passengers ; hence the total number of persons who arrived by the vessels shown in the above table cannot be given. Of the 319,167 passengers shown, 15,028 were troops, 2,519 pilgrims from the Hedjaz, and the remaining 301,620 chiefly passengers from ports near Bombay.

The following table shows the number of ships which had infectious disease on board on or before entering the harbour :—

Class of Vessels.	Number of Ships.	Total Number of Crew and Passengers.	Diseases and Number of Cases of Each.						Persons Number of Vaccinated.
			Plague.	Small-pox.	Measles.	Scarlatina.	Enteric Fever.	Number of Plague cases amongst suspects removed to Observation Camp on arrival of the vessel in Port.	
Entered	2	3,046	—	—	2	1	1	—	—
Pilgrim ships	—	—	—	—	—	—	—	—	—
Other vessels	11	3,987	14	3	1	5	—	—	111
Vessels with suspicious cases which turned out to be Plague after arrival.	60	—	—	—	—	—	—	65	—
Total	73	7,033	14	3	3	6	1	65	111
1896	14	9,104	2	3	5	3	1	—	601

Vessels which became infected while in port are not shown in the above table, but are noticed in the table on page 201.

The cases of Measles, Scarlatina and Enteric fever referred to in the foregoing table as having occurred on board the troop-ships were landed and isolated in the Military Cantonment at Colába. The Small-pox cases were removed to the hospital for infectious diseases on shore, and those persons unprotected among the crew and passengers were vaccinated. The 60 vessels shown in the table are those among whose suspected passengers and crew 65 plague cases occurred after the people had been sent to hospital for observation and disposal. The 11 other vessels with 14 cases of plague were those on board of which fully developed cases of plague were found at the time of arrival. They, as well as the 60 vessels shown in the table, came from infected ports in close proximity to Bombay.

Showing the number of vessels, crew and passengers examined on arrival at Bombay.

Months.	Number of Vessels Inspected.			Number of Persons Inspected.							Number of Persons Segregated.		
				Passengers.		Crew.		Total.			Segregated.		Number of crew and passengers.

Up to the 6th February, only vessels bound for European or other quarantine ports were inspected ; but after that date everything that floated was examined before it left the port, no matter for what place the vessel or craft was bound. The sanitary condition of all outward bound vessels was carefully attended to during the year. The crews' quarters were, as a rule, painted or lime-washed before departure. The inside of crews' boxes were treated in the same manner, and crews' clothes were exposed to the sun. Bilges in native craft were thoroughly cleaned and dried, and the holds of all vessels in ballast were swept clean and in most cases lime-washed or disinfected with carbolic acid lotion. The overcrowding of crews' quarters noticed in previous years was not marked during the year 1897. During the year the overflow pipes from the water tanks on board of some vessels were found to discharge directly into the bilges. This state of affairs was found on cargo, passenger and troopships. Such an arrangement as that referred to must be insanitary, more especially if the bilges are foul, as cockroaches, gases, &c., from the holds and bilges can find their way into the drinking-water tanks.

Infectious Disease on Vessels in the Harbour.—The following table includes all steamers, square-rigged vessels and native craft which became infected while lying in port, and is exclusive of those given in the first table on page 199, which became infected while at sea or whose passengers developed plague after arrival :—

Months.	STEAMERS.												BUGGALOWS, TONIES, PROWS, STEAM LAUNCHES, &C.												TOTAL NUMBER OF CASES OF INFECTIOUS DISEASE IN THE BOMBAY HARBOUR.

All the above vessels, including those in the table on page 199, were thoroughly disinfected in accordance with the rules laid down in the Venice Convention.

Disinfection of Ships and General Health of the Shipping.—Sixty-nine infected vessels of various kinds were disinfected during the year, under the personal supervision of the Port Health Officer or his staff assisted by the Water Police. The Director of the Royal Indian Marine saw that the disinfection of transports in which infectious diseases occurred was carried out in accordance with the recommendations of the Port Health Officer.

The health of the harbour population, estimated at 22,142, was fair. Exclusive of plague the total number of admissions into hospitals was 626. The St. George's admitted 438 Europeans, of whom 14 died; the Jamsetji 50 natives, of whom 3 died; and the Goculdas 138 natives, of whom 14 died.

Red Sea Pilgrim Traffic.—Owing to the plague in Bombay only 2 pilgrim ships left for Jeddah in January with a total of 1,106 pilgrims. After that date all Mecca pilgrims were prohibited leaving Indian ports. Over 600 pilgrims were in Bombay at the time waiting for a passage to Jeddah. Government kept them for 10 days in an observation camp and returned them to their homes in Hindustán and beyond the frontier at a cost of over Rs. 13,000. There were no cases of plague and no deaths on board the above two pilgrim ships between the port of Bombay and the Turkish Quarantine Station at Camaran.

During the year the following pilgrim ships arrived from Jeddah :—

S.S. "Pekin"—10th June with 1,021 souls (pilgrims), no deaths.
„ "Naseri"—10th June with 496 souls (pilgrims), 4 deaths.
„ "Mohomedi"—26th July with 519 souls (pilgrims), 13 deaths.
„ "Naderi"—13th August with 483 souls (pilgrims), 3 deaths.

The baggage of all the pilgrims who arrived by the S.S. "Mohomedi" and S.S. "Naderi" was disinfected by the Port Health Officer, as plague was reported to have broken out at Jeddah. The pilgrims were not allowed into the town, but were sent direct from the ship to their homes in batches at the expense of Government.

Sanitary State of the Harbour and Foreshore.—The foreshore was not inspected during the year owing to pressure of work.

Plague.

Many reports on the Bombay plague have been written, but so far no person has proved conclusively from where Bombay received the disease. Some say it was imported from China, while others affirm that it came from the slopes of the Himalayas. It seems to have escaped notice that plague is endemic in the Persian Gulf and the Red Sea Coast—places much nearer home than China—and that quarantine is imposed by Egypt and Aden almost yearly against that port of the Red Sea Coast between Leith and Lohaya and known as Assyr. On reference to the records it will be found that plague was epidemic in Assyr in October 1893, July 1894, August 1895, and October 1896.

As the organization for the medical inspection of all vessels and persons leaving Bombay by sea has been described in a special report by Surgeon-Lieutenant-Colonel MacCartie, M.B., C.I.E., and which will be found as an appendix in the official account of the Plague Administration in the Bombay Presidency for 1897, it is not necessary to go into the details again. The following short account of the harbour operations will therefore be sufficient. Several extracts are taken from Dr. MacCartie's report.

Outward Inspections.—During the earlier part of the epidemic, and up till 6th February 1897, only vessels and persons bound for European and other quarantine ports were inspected. As an exodus of the plague-stricken population of the city had set in, Government decided to have an examination of every vessel and native craft as well as of every crew and passenger which left Bombay by sea for any where. These wholesale inspections commenced on 6th February.

The object aimed at being the prevention of the spread of plague by sea to other Indian ports, to ports outside India, and, above all, to Europe, with its incalculable effects on Indian commerce. No measures were spared to obtain that end, and the most characteristic feature of the inspection became its extreme strictness and searching nature. Plague, moreover, is a disease which requires a very rigid and close inspection for its early recognition. Its main and chiefest signs during the Bombay outbreak were fever and buboes, and all natives with either of these signs became objects of suspicion, their temperatures were taken and they were subjected to the most searching examination in private. During the months of February, March and April the number of persons placed on one side for temperature observation ranged from 20 to 25 per cent., and as many as a dozen rapid registering thermometers were in use at the same time. It need hardly be said that to eliminate the suspicious cases a careful individual examination of each native was necessary, and this included not merely a look at a man's tongue and face and a pulse observation, but a careful exploration of his body for glandular enlargement. Nor was the examination confined to the persons sailing on a vessel. The vessel itself was overhauled and a high sanitary condition insisted on. This included the opening and thorough cleansing of lascars' boxes, which were often found to contain filthy clothes and rubbish quite capable of supporting the plague microbes in comfort and affluence. In fact, it would be impossible, humanly speaking, to devise a more stringent or exhaustive examination for the prevention of the export of plague.

All ship commanders were, in addition, advised as to periodical inspections of their crew during the voyage, and of the advantage of frequent exposure to sun and wind of lascars' clothes and kit, whilst printed instructions were sent to shipping agents for issue to commanders of vessels without medical officers, describing the symptoms and the treatment to be adopted should plague break out on their ships.

The strictness and thoroughness of the examination are described, and insisted on here, not because in the slightest degree do the officials, who carried it out, claim any credit for doing what was merely their duty, but because too much publicity cannot be claimed for the efforts made in Bombay to confine the plague within its own borders. It was noticed that neither lay nor even medical persons seemed to be able to realize how very searching the inspection was, until they had themselves experienced it. If then in India the real nature of the measures adopted by Government for the prevention of plague export cannot be conceived unless seen, it is not too much to expect that the nations of continental Europe, which have signed the Venice Convention, may also, without ocular or, at least, strong evidence, be unable to realize how great were the efforts made here to save them from the infliction which Bombay was enduring. Nor should it be forgotten that when the Indian Delegate at the Venice Convention described the thoroughness of the Bombay inspection, not from hearsay, but from the evidence of his own eyes, his statement was, according to Reuter, received with "satisfaction mingled with incredulity." At that very time, it may be added, a medical officer of the Italian Government, who had been sent to

Bombay to report on the measures adopted there for the prevention of the spread of plague to Italian ports, was expressing his surprise at the completeness of the inspection system here, and was learning from the evidence of his own eyes that the statement made by Dr. Cleghorn was true in every respect. This officer, Dr. Druetti, accompanied the Port Health staff to all vessels bound for Italian ports, generally assisted at the inspections, and became thoroughly acquainted with the Bombay measures of prevention ; and it was due to his favourable views, presumably, that the severe quarantine in force at Brindisi at the time was afterwards removed.

On a reference to the table on page 200 it will be observed that 40,565 vessels, including native craft, with a total of 710,716 outward bound crew and passengers were examined. It is of course impossible to accurately gauge what is the real and exact value to be attached to any system of medical inspection as a preventative to the spread of plague. It cannot discover the disease in its incubating stage, but it can detect signs and symptoms suspicious of the disease ; and if all persons with suspicious signs and symptoms are removed from a vessel, the odds are much in favour of that vessel remaining uninfected.

There is also an indirect effect which follows a strict inspection system, and that is the check on the spread of the disease which arises from plague and suspicious cases not caring to risk the chance of detection once the severe nature of the medical examination has been recognised. This was very marked during the first months of the inspections when it was noticed that, after the system had been acting for a short time, the number of plague and highly suspicious cases presenting themselves for examination considerably lessened.

When it is remembered that only two ocean-going steamers are known to have had plague on board after leaving Bombay from the first appearance of the disease in September 1896 to the present time, it is allowable to claim that the measures adopted by the Bombay Government shall be considered the leading factors in that result, and that a proper system of medical inspection if applied in time is capable of preventing plague from seriously spreading beyond its centre of first appearance to neighbouring parts. It is of course impossible to trace the movements of each passenger who left Bombay by sea for ports across the harbour, and down the coast ; and cases of plague may have got away, by sailing craft and small coasting steamers, even after the strict system of inspection was introduced for passengers by such vessels.

In all cases where plague developed among people who had been rejected from a ship, a telegram was sent to the next port of arrival warning them that a case of plague had been removed from the vessel.

The two ocean-going steamers mentioned above as plague-infected were the S.S. "Pekin," which left Bombay with 1,045 pilgrims for Jeddah on the 28th December 1896, and the hired Government Transport S.S. "Dilwara," which left Bombay for Southampton on 10th March with 172 crew and 1,063 passengers. The pilgrims of the "Pekin" had been in Bombay and living for weeks in a plague-infected locality, and, all things considered, it is wonderful that more cases did not occur.

During the year, 3,322 persons were prevented from sailing in vessels. All persons having any suspicious signs or symptoms of plague were rejected. As there were no camps of observation at the commencement of the year, to which such rejected cases could be sent for observation, they were allowed to return to their homes in the city, as it would not be fair to send them to a plague hospital. In the early part of the year only fully developed plague cases and markedly suspicious ones were sent to hospital. It is, therefore, impossible to give the number of cases which developed among those rejected and who were, therefore, prevented from leaving Bombay by sea, but the number of plague cases, of which we have a record, is 71, which is much below the actual figure.

Inward Inspections.—Large numbers of the city population, who had fled from Bombay in December and January, began to return as the plague declined. They had already scattered the disease far and wide over the Presidency, and they rushed back to the city, which they had abandoned in panic, with as much eagerness as they had originally left it. Public opinion, fearing the effects on the health of Bombay from this inrush of people, many of whom came from plague centres and famine districts, demanded some check on the importation of plague cases ; and, under the directions of the Plague Committee, the inspection of arrivals by sea from places within a defined area was organized and placed in working order.

Karáchi in the north was heavily infected, and the whole coast more or less as far south as Goa was either infected or in communication with infected places. Accordingly, Karáchi on the north and Bhatkal on the south inclusive were fixed as the limits of a

prescribed area from ports and places within which vessels on arrival at Bombay should be medically inspected.

These inward inspections were commenced in April, and a reference to the second table on page 199 will show that 32,187 vessels and 602,401 crew and passengers were examined. Of these incoming passengers, 39,199 were segregated for periods varying from 2 to 10 days. Those persons coming from very slightly infected ports, and who were suffering from fever, were kept under observation until their temperatures became normal, which usually took place in 1 or 2 days ; whereas those persons who came from heavily infected ports and from infected ships were detained for periods varying from 8 to 10 days according to the distance of the port from Bombay. Many of the above-mentioned 39,199 passengers, who were sent to the observation camps, were allowed out on the surveillance system. The heads of castes stood security and guaranteed that they would turn up periodically for medical inspection. Before such people were allowed out on surveillance certificates, they were photographed in groups and desired to present themselves at stated periods for inspection. The system is said to have worked well and few plague cases were found amongst them after the suspicious ones had been weeded out by the Port Health Staff. The actual number of plague cases detected at the inspections on arrival or that developed among those suspicious cases which had been isolated was 79.

The combined results of the inward and outward inspections as well as those in the harbour show that 72,752 vessels of all sorts were inspected, 1,313,117 crew and passengers were carefully examined, and 169 cases of plague discovered.

The Port Medical Staff have been engaged on a form of plague duty which is perhaps the most unpleasant that can be conceived. Cut off from almost all that interested them in their profession they have spent months and months on long and weary rounds of monotonous inspections. The exigencies of an enormous passenger traffic, and of commerce generally, necessitated hours of work which left little time for meals and none for recreation. Work began at 6 A.M. and rarely ended before 7.30 P.M. The public idea as to the simple nature of the inspections has been already alluded to and their real character explained.

Duties, which at no time were pleasant or easy, became too often loathsome and difficult. The exploring of some of the filthiest parts of the human body for enlarged or tender glands cannot under any circumstances be other than disagreeable ; and when this operation has to be repeated through days and weeks and months, it can only be described as nauseating and monotonous drudgery. Those only who have been through it can thoroughly appreciate how great was the sense of duty required to prevent, under such conditions, a searching examination from degenerating to a mere superficial and perfunctory observation.

ABSTRACT OF THE REPORT OF THE CALCUTTA MUNICIPALITY FOR 1897-98.

(*R. T. Greer, Esq., Acting-Chairman.*)

Town and Bustee Improvement.—The total amount spent by the Corporation on town and bustee improvements during the year 1897–98 was Rs. 57,340, against Rs. 52,576 in the preceding year. Exclusive of the outlay on latrines (Rs. 11,237) the total sum expended was Rs. 46,103, of which Rs. 37,917 was absorbed by town improvements, and only Rs. 8,185 on bustee improvements, construction of bustee roads, &c.

Waterworks.—The extensions of filtered water mains during the year aggregate 2·56 miles. The total length of filtered water pipes now amounts to 314·62 miles. The number of premises connected during the year amounts to 591, raising the total number to 27,775. The average daily consumption of filtered water during the year was 20,638,212 gallons, against 20,786,655 in 1896–97. The consumption of filtered water per head per day is estimated at 38·10 gallons in town and 11·26 gallons in suburbs, against 14·42 and 10·94 in the previous year.

The daily unfiltered supply was 5,461,823 gallons, and the daily consumption 12·51 gallons. A scheme for the extension of the unfiltered water-supply in the town area was carried out during the year at a cost of Rs. 5,46,254, the work being completed in March 1898. This has resulted in an extension of the unfiltered water main by over 15½ miles, the total length of pipe now amounting to 96·50 miles, with which are connected 1,906 premises, 135 public conveniences, 86 bathing platforms, 320 sewer flushing chambers, and 2,973 ground hydrants. The bathing platforms have since been disconnected from the unfiltered supply and reconnected to the filtered main. Besides this, a second project for extending the unfiltered water-supply in the suburbs is also being carried out, the length being estimated to be 221,700 feet and the cost Rs. 4,93,514.

Drainage and General Construction.—During the year 3·24 miles of pipe-sewers were entirely reconstructed to a new specification. 1·44 miles of kirb and channel stones were set in public streets. All the brick-sewers were carefully examined after the earthquake of 12th June 1897, and as a result of this examination, 1·12 miles were repaired and cement-pointed. The main outfall sewer between Circular Road and Palmer's Bridge silt-pits appears to have suffered most, and it was necessary to put in 663 lineal feet of strong tie-rods and to wedge all the cracks. There have been constructed during the year 54 new gully-pits, 28 sewer man-holes, 31 sewer lamp-holes and 10 flushing chambers, fitted with Miller's patent automatic syphons. The sewers including 9·42 miles of bustee sewers now measure about 200 miles. Of works of public convenience, 3 bathing platforms have been completed and brought into use ; 4 have been thoroughly repaired ; 1 night-soil pail depôt of large size has been constructed, and 2 thoroughly repaired and improved. One 12-seated latrine on the "model trough" system has been constructed ; as also a 4-seated latrine with white-glazed tiles. Besides these a combined latrine and urinal for gentlemen and a retiring-room for ladies have been constructed in the north and south quadrangles of the New Market. 12 public latrines have been thoroughly repaired. 5 Bombay pattern urinals with white-glazed tiles have been constructed in public streets, and 10 have been repaired. 2 mehters' barracks have been reconstructed. 3 hackney carriage stands have been constructed, paved with stone-setts. 317,250 tons of refuse were conveyed by the Municipal Railway to the square-mile and unloaded, as compared with 307,200 tons in the previous year. In addition to this, 19,478 tons of road metal and building materials were hauled from the store depôt at Bagh Bazar and unloaded at the various sub-depôts in Circular Road.

The quantity of refuse removed from the town is increasing year by year. An increase of 23,000 tons appears in the quantity hauled down to the square-mile and unloaded, and a further increase of 10,000 tons during the year under report.

House Drainage.—The number of premises connected with the public sewer during the year was 260, bringing the total up to 29,848. The drains of 8,601 premises were inspected during the year, and out of this number 2,955, or 34 per cent., were found more or less defective. Notices to rectify, specifying the defects, were issued in all cases ; 9,176 re-inspections also were made. The number of privies connected with the sewers under the new rules was 31, bringing the total up to 1,084.

Roads.—The total length of roads on 31st March 1898, within municipal limits, was 331 miles 4 furlongs and 115 feet, of which 104 are stone metalled, 165 brick metalled, 35 over sewered ditches, and 25 unmetalled.

Price of Food.—Owing to the extensive failure of crops in the country the price of food exceeded the average of the ten preceding years. The price of common rice, which averaged Rs. 4–0–5 per maund during the previous ten years, in 1897–98 rose to Rs. 5–2–3 per maund.

Health of the Town.—The birth-rate was the same as in the preceding year (18·4 per 1,000), but showed an increase on the average of the preceding eight years. The death-rate was higher than in any of the previous eight years, with the single exception of 1895. The figures are shown as follows :—

Year.	No. of Deaths.	Death-rate.
1889	19,564	28·7
1890	20,368	29·8
1891	21,517	31·5
1892	20,180	29·6
1893	20,103	29·5
1894	22,441	32·9
1895	27,031	39·6
1896	24,356	35·7
1897	25,665	36·1

Special attention has been again drawn by the Health Officer in his report to the increased mortality among infants under one year of age, and suggestions have been made for the better regulation of the milk-supply of Calcutta.

The increase in the general mortality, as compared with the figures of the preceding year, was due to an increase under all causes excepting cholera which showed a decrease. Deaths from small-pox were comparatively few, being only 161 against an average of 467 for the eight years from 1889 to 1896. 17 of these cases are traceable to Howrah and other places beyond the limits of Calcutta. On the other hand, death from fevers as well as from diarrhœa and dysentery, though fewer than in the year 1895, considerably exceeded the average of the eight years preceding 1897 ; while deaths from causes other than cholera, small-pox, diarrhœa, dysentery and fevers largely exceeded the corresponding figures of each year from 1889 to 1896. The annual number of deaths from fevers in urban Calcutta in the past four years was the highest recorded in any of the past 29 years with the single exception of 1878. The highest number of deaths in suburban Calcutta recorded in any year since the amalgamation was that of 1897.

Special stress is laid in the Health Officer's report on the defective registration of births and of causes of death. It is suggested by him that private cemeteries for the disposal of the dead should not be permitted in Calcutta, and that the neighbouring municipal and district authorities should be asked to supply this Corporation with regular returns of cremation and burial of persons within their jurisdiction dying in Calcutta.

The precautions taken against the plague were briefly—

(*a*) The division of the city into 17 (subsequently into 10) circles, each under a qualified medical man.

(*b*) The medical inspection of persons arriving in Calcutta from places infected by plague, and the inspection of lodging-houses and grain-depôts in Calcutta.

(*c*) The completion of a plague hospital at Manicktola and the elaboration of a complete scheme, including sites for the construction of plague hospitals within the city to combat an outbreak of plague.

(*d*) The addition of a hand ambulance of the pattern employed at Bombay.

(*e*) The provision of an equifex disinfector and an equifex disinfecting sprayer, both worked by steam, and a force-pump for flushing *gullies* ; also the laying in of a stock of disinfectants.

(*f*) The continuation of the post of Chief Superintendent of Conservancy to supervise the town cleansing and sanitary departments under the Health Officer, and the appointment of a special staff for cleaning and lime-washing filthy localities and unclean houses.

This establishment at first consisted of 2 superintendents, 1 inspector, 13 sub-inspectors, 1,500 coolies and 343 carts. It was subsequently reduced to 498 coolies only ; again increased to 1 superintendent, 3 inspectors, 12 sub-inspectors, 665 coolies, 57 carts and 3 sweeping-machines ; and finally reduced to 1 superintendent, 1 inspector, 6 sub-inspectors, 403 coolies and 54 carts.

Owing to an outbreak of small-pox in Howrah and neighbouring places, and its moderate prevalence in Calcutta, the number of cases of vaccination rose from 11,976 in 1896–97 to 21,620 in the year under review. This number largely exceeds that of any previous year since 1892 except 1895, the figure for which is exceptionally high owing to the abnormal prevalence of small-pox in the town in that year.

Anti-choleraic inoculation according to Haffkine's method was practised during the first three months of 1897.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR 1897.

(*Dr. J. Nield Cook.*)

The period under report saw some changes in the post of Health Officer of Calcutta. Dr. W. J. Simpson, who was Health Officer from the 1st January to the 6th September 1897, retired before a permanent successor to him had been appointed, and Dr. R. Sen was appointed to act until I was elected and joined on the 7th January 1898. As I only held office for a short period during the year under review, the greater part of the report has been written by Dr. Sen and only revised by me.

Meteorological Condition and Food and Water Supply.—The variations in the atmospheric pressure during the greater part of the year 1897 were small, the lowest reading 29·540 being recorded in June, and the highest 30·021 in December. The mean daily variations of temperature were, as in the previous year, greatest from January to June and from October to December, and least in August. The mean maximum solar radiation was highest in April and May. The atmospheric humidity was greatest in August and least in April. Rain fell during all the months except November and December, the number of rainy days during the year amounting to 128. A total of 58·33 inches of rain fell during the year, and the maximum monthly total rainfall and the maximum fall in 24 hours both occurred in July.

Price of Food.—The price of food was much higher in 1897 than the average of the preceding ten years. Common rice was sold on the average at Rs. 5–2–3 against Rs. 4–0–5 per maund. Oil (mustard) and salt sold at prices higher than the mean of the previous ten years, but fuel was cheaper. Meat and other articles were sold at the Municipal Market at rates higher than the average of the previous ten years.

Water-supply.—The quantity of filtered water for drinking and other domestic purposes supplied to the town averaged over 30 gallons daily per head of the population. The supply maintained its general purity throughout the year.

Vital statistics.

Births.—The number of births (children born alive) recorded during the year 1897 was higher than that recorded in five out of the previous eight years. There were 12,584 births, giving an annual birth-rate of 18·4 per 1,000 of the population. The figures for the past nine years are as follows :—

Year.	No. of Births.	Birth-rate per 1,000.
1889	12,317	18·0
1890	11,918	17·4
1891	12,477	18·3
1892	12,688	18·6
1893	13,492	19·7
1894	11,438	16·8
1895	10,945	16·0
1896	12,608	18·4
1897	12,584	18·4

As usual, the highest birth-rates were those of the Christians and "other classes," and the birth-rate was greater among the Hindus than among the Mahomedans. The greater birth-rate among Hindus than among Mahomedans appears to be due, at least partly, to the Hindu population being in the main more residential in character than the Mahomedan population of Calcutta. According to locality, the birth-rate was greatest in added area of Burtollah, Ballygunge, Hastings and Baniapooker wards, and was least in Waterloo

Street and Park Street wards. The male births fell below the female births in only three districts, namely, the added area of Moocheepara, Baniapooker and Khidderpur, and male and female births were practically equal in one district, namely, Puddopooker. In all the remaining wards the male births exceeded the female births, the excess being greatest in the added area of Shampooker and in Bamum Busti, Burrabazar and Colootola wards.

General Mortality.—The general mortality of the town during 1897 was greater than that of the previous year, and also exceeded the average of the preceding five years. There were 24,665 deaths from all causes, being a mortality of 36·1 per 1,000 of the population against 24,356, or a ratio of 35·7, in 1896, and against 22,822, or a ratio of 33·5, the mean of the five years from 1892 to 1896. The following figures give the numbers of deaths and death-rates in Calcutta during the past nine years, namely,—

Year.	No. of Deaths.	Death-rate per 1,000.
1889	19,564	28·7
1890	20,368	29·8
1891	21,517	31·5
1892	20,180	29·6
1893	20,103	29·5
1894	22,441	32·9
1895	27,031	39·6
1896	24,356	35·7
1897	24,665	36·1

A decline in the public health of Calcutta was noticed in the reports of 1895 and 1896. A similar decline in the public health is noticeable in the year 1897. In comparison to the previous quinquennium, this decline was greater in the suburban area than in the old town area, and in the area bordering on the circular canal than in the rest of the suburbs. The death-rate in urban Calcutta rose to 32·2 in 1897 against 30·4 the average of the previous five years, while the death-rate in the suburbs rose to 44·7 against 39·9 the mean of the previous five years ; and the ratio in the canal area was 43·6 against 39·4, and in the rest of the suburbs 35·7 against 34·0. When a comparison is made with the year 1896, however, it is noticed that, while there was an improvement in the general health of all the urban wards except Shampooker, Coomartooly, Jorabagan, Burrabazar and Moocheepara, there was a deterioration in the suburban parts of three out of the four extended wards as well as in three out of the seven suburban wards.

The incidence of mortality, as usual, varied greatly according to age. Thus, out of the 24,665 deaths that took place during the year, no less than 6,817, or more than a fourth part, occurred within the first five years of life ; and while only 2,924 deaths, or 11·8 per cent., took place between five and twenty years of age, 6,710 deaths, or 27·2 per cent., occurred between the ages of twenty and forty, 4,153 deaths, or 16·8 per cent., between forty and sixty, and 4,061, or 16·4 per cent., from sixty years upwards. If the numbers of deaths at different ages be considered in relation to the proportion of the population at those respective ages, it is seen that while the death-rate per 1,000 of the population between the ages of five and sixty is not excessive for an oriental city, that between the ages of one and five years is at least five or six times what it should be in a healthy town, and that under one year of age amounts to 458·5 per 1,000, which is proportionately at least as excessive.

In comparison to the previous year there was an increase in the death-rate under five years of age and between ten and forty years, but a fall in that between the ages of five and ten and from forty years upwards ; but the increase in the one case was in excess of the decrease in the other, so that the total death-rate for all ages during 1897 exceeded that of 1896. The figures are as follows :—

Year.	Under 1 year.	1 to 4 years.	5 to 9 years.	10 to 19 years.	20 to 39 years.	40 to 59 years.	60 years and upwards.	Total.
1896	435·4	50·4	22·3	17·1	24·2	28·5	74·0	35·7
1897	458·5	58·3	21·8	17·7	26·2	26·6	69·3	36·1

The mortality of infants under one year of age during 1897 was extremely high, and though below the figure of 1895 exceeded that of 1896. There were 4,491 deaths, being a mortality of 356·5 per 1,000 births. The mortality was much greater in the urban than in the suburban area of Calcutta, being 379·7 against 320·3 per 1,000 ; and it was greater in males than in females, and was, as usual, greatest among the Mahomedans and least among the Christians.

The subject acquires a really serious import when one compares the statistics of infant mortality in Calcutta during the past few years, as in the following table :—

Year	1897	Mean of previous 5 years	1896	1895	1894	1893	1892
Death-rate per 1,000 infants under one year of age.	458·5	422·0	435·4	476·0	402·4	415·4	383·9

These figures serve to show that not only was the infant mortality in 1897 in excess of the average of the previous five years, but, what is perhaps of still greater consequence, that the mortality among infants has been almost steadily increasing since 1892. The alarming state of things disclosed by these statistics calls for speedy attention from the sanitary authority of the city. In the report submitted by the late Health Officer, Dr. Simpson, on the health of Calcutta for the year 1895, attention was drawn to the highly insanitary condition of Calcutta implied in the figures of its infant mortality ; and as the subject is one which should not be lost sight of the remarks made by him in 1896 may with advantage be repeated.

" The high mortality among infants is a prominent and discreditable feature of Calcutta, " and urgently calls for improved sanitation in connection with the construction and " cleanliness of dwellings and the proper regulation of the milk-supply, in addition to an " improvement of the general drainage and cleanliness of the town. Though a good deal " of any improvement in the health of the infant population will, in the long run, depend " on the spread of sanitary education among the masses and particularly among the female " section of the community, a considerable part of it lies within the range of public " hygiene ; and this particularly applies to the laying down of proper rules and regula- " tions for the construction of sanitary dwellings and for the control of the milk-supply " of Calcutta, to the removal of the defects in the general drainage, and to the adoption of " proper means to secure an efficient daily cleansing of the town."

With regard to measures for the removal of these insanitary conditions, it may be mentioned that the Building Commission, whose appointment by Government was noticed in the last annual report, has completed its labours and submitted its report, making definite recommendations for the improvement of the building regulations of Calcutta ; and legislation to secure the construction of sanitary dwellings has been taken in hand along with that intended to remove other sanitary defects which exist in the town. Practical measures for the improvement of the drainage of Calcutta have been adopted and are being carried out. The Commissioners have, moreover, shown a general inclination to adopt means to secure an efficient daily cleansing of the city ; and, as an earnest no doubt of what they eventually mean to do, they have already made an addition to the town cleansing establishment, and appointed a special officer responsible for its cleanliness. The cleansing establishment is, however, much below the minimum necessary for good conservancy, and the Corporation is partly dependent on hired carts and cattle for removing the refuse. The proper regulation of dairies and the milk supply of the city still remains a *desideratum*, and should be delayed no longer. In this connection the chief measures, which I think are worthy of consideration, are the setting apart of suitable localities for cowhouses in sparsely populated parts of the town, the construction or remodelling of all cowhouses and dairies on approved sanitary patterns, and the abolition of the sale of milk or its products by itinerant vendors having no fixed dairies or shops in Calcutta.

As usual, the mortality among females was higher than among males, the ratio being 42·4 to 32·9. The excess in mortality during 1897 over the average of the previous five years was due to a rise in the mortality among both males and females.

The death-rate according to nationality was lower among Christians and Mahomedans, but higher among Hindus and other classes, than the average of the previous five years. The figures for 1897 are 22·6 for Christians, 32·1 for Mahomedans, 38·7 for Hindus and

51·9 for Other Classes, against 24·7, 32·8, 34·2 and 48·5 the averages of the previous five years, respectively.

The mortality that took place in the town during the year 1897 is shown, ward by ward, in comparison with the average mortality of the previous five years in the statement subjoined. It will be observed that there has been an improvement in the public health in the European quarter generally in the old town area, the district of Waterloo Street alone forming an exception, and that a similarly satisfactory condition of the public health has been attained in the Puddopooker Ward in urban Calcutta, as well as in the added area of Shampooker and in the Baniapooker, Ballygunge and Bhowanipur wards in the suburbs, the improvement in the public health during 1897 over the previous quinquennium being most marked in the Colingah, Park Street and Ballygunge wards. On the other hand, there has been a marked falling off in the health of the native quarters of Calcutta, the deterioration being most conspicuous in Entally, the added area of Moocheepara and Burrabazar.

In the subjoined statement is shown, under five causes or groups of causes, the mortality that took place in 1897 in comparison with that of previous years. It will be observed that, though in comparison with the year 1896, the year 1897 was characterised by a fall in the mortality from cholera, but a rise in that from all the remaining causes, still when the comparison is made either with the average of the previous five years, or with that of the preceding eight years, there has been a rise in the mortality from all causes excepting small-pox, that is to say, from the factors which habitually create the bulk of the mortality in Calcutta.

Statement of Deaths from the five principal causes in Calcutta during 1897 *compared with the mean of the preceding decade.*

Small-pox.—The mortality from small-pox during the year 1897, though it exceeded the corresponding figure of the preceding year, was much lower than the average of the previous five years. The number of deaths recorded under this head amounted to 161, against 69 of the previous year, and against 469 the average of the preceding five years (1892 to 1896). Were we to exclude the 17 deaths which occurred in the Campbell Hospital among patients admitted there from places beyond the limits of Calcutta, the number of deaths that could be ascribed to Calcutta proper would be only 144. Of the 161 deaths, 82 occurred in urban and 79 in suburban Calcutta. The cases were distributed through the town, only four wards, namely, Waterloo Street, Park Street, Bamun Basti, and Hastings, being free from the disease. 103 of the cases were unprotected, 30 vaccinated, and 20 inoculated, and 1 had had natural small-pox, while in 7 cases previous protection or otherwise was not ascertained.

Cholera.—The mortality from cholera during the year 1897 exceeded that of every year since the amalgamation of the suburbs with the town of Calcutta, excepting 1891 and 1896, and also succeeded the average of the eight years from 1889 to 1896. The number of deaths was 2,349 against 2,160 the mean of the eight years from 1889 to 1896, giving a death-rate of 3·4 against 3·1 per 1,000 of the population. Of these 2,349 deaths, 1,543 took place in urban Calcutta, exceeding the mean of the preceding ten years by 225, and 806 in suburban Calcutta, falling short of the average of the previous eight years by 73. The figures for the two areas are as follow :—

Total Calcutta ...	1,198	1,734	2,315	1,879	2,955	2,019	869	1,695	2,099	3,449	2,349

The mortality from cholera according to season is shown by the following figures :—

January.	February.	March.	April.	May.	June.
124	325	646	522	252	189
July.	**August.**	**September.**	**October.**	**November.**	**December.**
88	27	42	36	59	39

From these figures it will be seen that the heaviest mortality during the year was, as usual, in March and April. The mortality was greatest in Coomartooly, Entally and the added area of Shampooker, with death-rates of 5·8, 5·8 and 5·4, respectively, per 1,000 of the population, and was lowest in Collinga, Baniapooker and Khidderpur, with a death-rate of 1·3 per 1,000 of the population in each. One ward, namely, Park Street, was entirely free from the disease during the year. The average cholera ratio 3·4 was exceeded in seven wards of the urban area, in the extended parts of Shampooker and Coomartooly, and in Entally and Bhowanipur in the suburban area. In connection with the prevalence of cholera, bacteriological examination was made of 839 samples, mainly of water from the river Hooghly, Circular Canal, Tolly's Nullah, tanks and wells, bathing platforms, house taps and reservoirs in pumping stations ; of these, 602 samples examined during the first half-year from January to June showed the presence of *comma bacilli* in 57 or 9·4 per cent., though none of the samples of filtered water did so, while 237 samples examined during the latter half of the year gave no indication of *commas*.

In the annual report for 1896 it was stated that owing to the discovery of *comma bacilli* in a large number of the public bathing platforms synchronously with their presence in the river water opposite Calcutta and with the prevalence of cholera in the town, the supply of unfiltered water at these platforms had been considered a danger to

the public health, and it had been recommended that filtered water should be supplied to them instead. This recommendation was accepted by the Commissioners and carried into effect during the year under review.

Bowel-complaints.—The mortality from dysentery and diarrhœa was higher in 1897 than the average of the previous eight years. The number of deaths was 3,218, against 2,856 the mean of the eight years from 1889 to 1896, giving a death-rate of 4·7 against 4·1 per 1,000 of the population. Of the 3,218 deaths, 1,449 occurred in urban Calcutta, exceeding the average of the previous decennium by 78, and 1,769 took place in suburban Calcutta, exceeding the mean of previous eight years by 345.

Fevers.—The deaths from fevers during the year 1897 were in excess of those in 1896, and also exceeded the average of the previous eight years. The total number of deaths recorded during the year was 9,619 against 9,564 in 1896 and against 8,277 the mean of the eight years from 1889 to 1896, equivalent to a death-rate of 14·1 against 14·0 and 12·1 respectively per 1,000 of the population. The figures for the urban and suburban areas are severally shown in the following table :—

Year.	Urban Calcutta.		Suburban Calcutta.		Total Calcutta.	
	Number of deaths.	Death-rate.	Number of deaths.	Death-rate.	Number of deaths.	Death-rate.
1897	5,954	12·7	3,665	17·0	9,619	14·1
1896	6,075	13·0	3,489	16·2	9,564	14·0
Average of 8 years 1889–96 ...	5,021	10·7	3,256	15·1	8,277	12·1

From these figures it will be seen that, in comparison with the year 1896, there was a slight fall in fever mortality in the urban area but a rise in the suburban area, though the excess in the latter case being greater than the fall in the former, the mortality in the town as a whole somewhat exceeded that of 1896. On the other hand, in comparison to the average of the eight years from 1889 to 1896, there were 933 more deaths in urban Calcutta and 1,342 more deaths in suburban Calcutta in 1897. A glance at the annual figures for the past nine years, in fact, renders it apparent that the death-rate from fevers in 1897 is not far from being double of what it was in 1889 in the urban area of Calcutta, while it is also largely in excess of that of 1889 in the suburban area. This appears from the following figures, which also show the relation between the fever ratio and the high price and consequent scarcity of food during the past nine years :—

Deaths and death-rates from fevers in Calcutta during 1897.

Year.	Urban Calcutta.		Suburban Calcutta.		Total Calcutta.		Price of common rice.
	No. of deaths.	Ratio.	No. of deaths.	Ratio.	No. of deaths.	Ratio.	
							Rs. A. P.
1889	3,341	7·7	2,653	12·3	5,994	8·8	3 5 0
1890	4,154	8·9	2,638	12·2	6,792	9·9	3 2 0
1891	4,675	10·0	3,176	14·7	7,851	11·5	3 8 9
1892	4,632	9·9	2,986	13·8	7,618	11·1	4 6 0
1893	4,749	10·1	3,342	15·5	8,091	11·8	4 10 0
1894	5,712	12·2	3,251	15·1	8,693	13·1	4 9 4
1895	6,831	14·6	4,514	20·9	11,345	16·6	3 12 0
1896	6,075	13·0	3,489	16·2	9,564	14·0	4 14 6
1897	5,954	12·7	3,665	17·0	9,619	14·1	5 2 3

It will be observed that, with the exception of 1895, which was a specially unhealthy year in respect of fevers not only in Calcutta but in the province of Bengal as a whole, and excepting some slight variations, the death-rate has risen during the past nine years

in almost the same proportion as the price of food, giving the high ratio of 14·1 per 1,000 of the population, which is not much below half of the total death-rate in the year 1897, when food rose to a scarcity price.

Other causes.—The mortality from all other causes during 1897 exceeded that of all of the previous eight years and also exceeded the average of those years by 1,132. There were 9,318 deaths, against 8,307 in 1896 and against 8,186 the mean of the eight years from 1892 to 1896, giving a death-rate of 13·6 against 12·2 and 12·0 respectively.

Registration of births and deaths.—For the purpose of registration of births and deaths the city is divided into 25 districts, called wards, placed in charge of 25 officers called Sub-Registrars of births and deaths, who work under the general supervision of 24 Ward Inspectors. The Ward Inspectors, however, are officers entrusted with and responsible for the daily town cleansing work and the adoption of measures for the abatement of nuisances in their respective wards, and the Sub-Registrars, who are men of the sircar class, are mere indoor clerks, and have to assist the Inspectors in the clerical work connected with the town cleansing and sanitary department. This complication of duties entrusted to the same officers leads to the registration of births and deaths being ill-performed, owing to its being left mainly, if not altogether, to the discretion of the residents.

Under the local circumstances, the complete registration of births taking place in Calcutta requires that there should be an efficient organization by which all births occurring in the town should be promptly brought to the notice of the ward officers concerned. From the want of such an organization it happens that in case the parents or friends of newly born children neglect to present themselves at the ward offices, the births are rarely discovered by the registering officers, though occasionally a few such cases are detected by the Ward Inspectors, either through their own establishments or through the vaccinators and Medical Inspectors or otherwise. When unregistered cases of birth, however, are so detected, prosecution is instituted against the parties responsible for the offence. In this way 36 prosecutions were undertaken or conducted during the 12 months from 1st April 1897 to 31st March 1898, of which 32 were disposed of, with an aggregate penalty of Rs. 54–8 imposed after conviction on the offenders.

As regards the registration of deaths which take place in Calcutta, the work is better done, owing to the arrangement which exists for the supply of death returns from the chief public cremation grounds and cemeteries in the city to the death registration department of the Corporation. Although, in consequence of the corpses of persons who die in Calcutta going as a rule to those cremation grounds and cemeteries or at the ward offices, a small margin is often left of cases in which the bodies of the dead are disposed of either at places beyond Calcutta or in cemeteries in town with which no arrangement exists for the supply of death-returns. This defect ought to be removed by arranging with the owner or person in charge of every cemetery in which the bodies of persons dying in Calcutta are accustomed to be disposed of, for the registration of the deaths and the supply of returns to the Corporation.

The main defect in the registration of deaths in Calcutta, however, consists in the fact that the cause or causes to which deaths are ascribed in the death registers are, when enquired into, found in many cases to be wrong, rendering the death statistics of the town in respect of the causes of death unreliable. As stated in the annual report for the year 1891 and as may be ascertained by analysing the deaths registered during any year, more than half of the people who die in Calcutta are not attended in their last illness by a medical practitioner of any sort, while the number that are attended by qualified medical men is very much smaller, generally not exceeding 20 per cent. So that in a large majority of deaths taking place in the town the causes of death recorded in the death registers cannot be depended upon ; and even in the cases which receive qualified medical attention before death, as the production of a medical certificate before the disposal of a dead body cannot be insisted on, the causes of death recorded at the cremation grounds and cemeteries in the majority of instances depend on the mere statement of the friends of the deceased.

Cremation grounds and cemeteries.—The disposal of corpses is carried on in Calcutta indifferently by day or night, specially as regards the cremation of Hindus. There are 3 public cremation grounds and 1 public cemetery for Hindus, 4 public cemeteries for Mahomedans, 4 for Christians, and 1 for Jews, where either officers called Sub-Registrars are employed by the Corporation for the registration of deaths or an arrangement exists with the registering officers in charge for the supply of weekly death returns.

Of these the cemeteries for Christians and Mahomedans are in charge of two Burial Boards appointed by Government, both of which have the Chairman of the Corporation for their President; while the three cremation grounds and one cemetery for Hindus are in charge of the Corporation.

There are, however, many places in Calcutta for the disposal of the bodies of persons dying in the town, which are owned by and are in charge of private individuals, and which are used either as family burial grounds, or as cemeteries for special small communities. There is at present no proper arrangement to ensure that every case of burial taking place in these cemeteries will be invariably registered and timely reported to the Corporation, though the number of burials taking place in them annually is very small, and some of them have even no burial at all for a year or more. This defect in respect of registration of deaths in private burial grounds and supply of returns to the sanitary authorities of the city needs rectification as early as possible.

For the convenience of the Hindu public the rates fixed for the supply of fuel and other necessaries of cremation were reduced in the course of the year under report. Four public Mahomedan cemeteries, moreover, were closed as unfit for further burials, and a new one, called the Gor-i-Ghariban, was opened at 32, Gobra Road. Steps were also taken to acquire a plot of land for a new Mahomedan cemetery to serve the northern part of the town. The owners (three) of one of the old Mahomedan cemeteries which had been closed were prosecuted for permitting illicit burials to take place there, and one of them was twice convicted and fined. Fifty-one persons who buried corpses in the cemetery were also prosecuted and were convicted and fined in amounts varying from Rs. 2 to Rs. 10 each. But, as in spite of these measures clandestine burials continued, and the owners pleaded their inability to prevent them for want of guards, special guards have recently been appointed at their expense for the detection of illicit burials which may take place there. This case shows the necessity for public cemeteries, like cremation grounds, being placed under the direct authority of the Corporation or of some responsible constituted body like the Christian or the Mahomedan Burial Board. It also seems to me that no cemetery of any sort which is not under the immediate control either of a special Board appointed by Government or of the Corporation should be allowed to exist in Calcutta, and that, to meet the wishes of those who might prefer to have places for the exclusive use of themselves and their relatives and friends for the disposal of corpses, special plots might be set apart in every public cemetery kept open in the town.

Vaccination.—Vaccination against small-pox was carried on as usual by the vaccination department of the Health Officer during the year 1897; and owing to the prevalence of small-pox in the town, as well as in Howrah and adjacent places, a much larger number of operations were performed during the year than in the previous year. The total number of persons vaccinated was 21,620, against 11,976 in the previous year. Of these, 13,297 were primary operations and 8,323 were cases of re-vaccination, against 9,450 and 2,526 respectively in 1896, thus showing an increase of 3,847 primary vaccinations and 5,797 re-vaccinations.

Besides the above numbers, which show the work done by the vaccination department, under the Health Officer, 97 primary vaccinations and 2,898 re-vaccinations (so far as ascertained) were performed by Government officers of the Animal Vaccination Depôt, Calcutta, in private European houses and in public institutions (such as hospitals, jails, asylums, &c.). These figures have not been included in the Health Officer's vaccination returns, and are stated here merely to show that a considerable number of persons, mainly Europeans, find it convenient to have vaccination done by others than the vaccination officers under the Health Officer. Were these figures, however, combined with those shown in the returns of the Health Officer, the total number of primary operations done in Calcutta during the year 1897 would amount to 13,394 and the number of re-vaccinations to 11,221.

Of the 13,297 primary operations performed by the Health Officer's establishment, 12,308, or 92·56 per cent., were successful, 283, or 2·12 per cent., unsuccessful, and 20, or 0·15 per cent., were doubtful, while in 686, or 5·15 per cent., the result could not be ascertained. The rate of success calculated on the ascertained cases was 97·59 per cent. Of the 8,323 re-vaccinations 912, or 10·95 per cent., were successful, 3,455, or 41·51 per cent., were unsuccessful, and 1,156, or 13·88 per cent., were doubtful, while in 2,800, or 33·64 per cent., the result could not be ascertained. Calculated on the ascertained cases, however, the rate of success in the re-vaccinations was 16·51 per cent.

Of the total of 21,620 persons vaccinated 12,814 were males and 8,806 females; and according to nationality 14,224 were Hindus, 4,883 Mahomedans, 2,400 Christians and 113 of other classes. Considered according to age 4,467 of the vaccinated were under 1 year, 8,622 were 1 year and under 6 years, and 8,531 were 6 years and upwards.

Of the 13,297 primary operations performed in 1897, 9,201 were Hindus, 3,601 Mahomedans, 416 Christians, and 79 other classes; while 4,467 were under 1 year of age, 5,982 were 1 year and under 2 years, 2,317 were 2 and under 6 years, and 531 were 6 years and upwards.

Primary vaccination is carried on in Calcutta under the Compulsory Vaccination Act, which provides that the parent or guardian of a child is to get it vaccinated within one year from birth, and that if on the expiration of that year the child is found unvaccinated, the parent or guardian may be prosecuted and an order obtained from a Magistrate for the compulsory vaccination of the child. The procedure accordingly adopted is for the Registrar of Births, at the time of registration of a birth, to issue a notice to the parent or guardian of the child to get it vaccinated within 12 months from the date of birth, and to send a corresponding notice of the birth to the vaccination department; and for the vaccination department, as soon as possible after the child has been vaccinated, to grant to its parent or guardian a certificate showing the result of the operation, and to send a corresponding certificate to the Birth Registrar for record. When twelve months have elapsed from birth, if the child is found unvaccinated, though in a fit state to be vaccinated, prosecution is instituted against the parent or guardian. Under the powers conferred on the vaccinators by the Amended Vaccination Act, moreover, house-to-house enquiry is made for unprotected persons by the male and female vaccinators of the department, and for every person over one year of age who is found unprotected and who or whose parent or guardian refuses to have vaccination done, a notice is issued to have the operation performed within 15 days from the receipt of notice, and, in default, the party responsible is prosecuted.

The residents mostly have a disinclination to have their children vaccinated until they are at least a year old; and the Vaccination Act gives them an undesirable latitude in this respect. Hence it happens that of the children born in Calcutta during any year only a certain number are vaccinated in the course of that year, while the balance that remain available for vaccination have to be dealt with during the year following; and as a considerable proportion of the population of the town of all ages is floating in character, some of the children born in Calcutta that have not been vaccinated or have not died during the first year of birth totally escape vaccination, either by removal from the town or by their whereabouts being not traceable after twelve months, by which time the children born in the town and those of the same ages imported from elsewhere have become mixed together, rendering differential enquiries extremely difficult. There are, however, no data available from which the proportion of children under 1 and 2 years leaving or coming to Calcutta can be even approximately estimated.

Of the 12,608 children born in 1896 4,265 died in that year, leaving 8,343 available for vaccination. Of these 8,343 children 2,936 were vaccinated during 1896, thus leaving a balance of 5,407 at the beginning of 1897. This figure, 5,407, when compared with 5,982, the number of children between 1 and 2 years of age actually vaccinated during 1897, and specially when due allowance has been made, first, for the number that died in 1897, and, secondly, for those of the same age that came into or left the town during the same period, serves to shew that few of the children born in Calcutta during the year 1896 have escaped vaccination. Although the protection of the infant population, so far as the children born in Calcutta are concerned, cannot be considered altogether unsatisfactory, that protection takes two years' time for its accomplishment; so that a large proportion of the population remains unprotected for over a year from birth. This defect in the due and early protection of the infant population of Calcutta can be only remedied by a reduction of the period from birth during which compulsory vaccination cannot be legally resorted to.

Vaccination was performed during the year 1897 mainly with lymph obtained direct from vaccinated calves, of which the department received a supply of 566 in the course of the year from the Government Animal Vaccination Depôt in Calcutta. But in some cases, and specially in vaccination done among the poor at their own homes, lanoline paste obtained from the same source was made use of for convenience; and in a few cases humanised lymph was employed when people objected to vaccine taken from calves. The following table shows the comparative rates of success in primary vaccination obtained

from the use of direct calf lymph, lanoline calf lymph and humanised lymph, respectively :—

—	Direct calf lymph.	Lanoline paste.	Humanised lymph.
Total No. vaccinated	10,081	2,400	816
No. in which result was ascertained	9,786	2,014	811
Rate of success per cent. on ascertained cases	97·32	98·01	99·87

The low percentage of success obtained with vaccination from calf to arm compared with that with preserved lanoline paste is difficult to account for unless some of the calves used had passed the period of greatest efficacy, as in my experience the use of lanoline paste necessitates more excoriation and more rubbing in than lymph direct from the calf.

Anti-choleraic inoculation.—Inoculation according to Professor Haffkine's method as a preventive against cholera was practised on persons who voluntarily submitted to the operation during the first three months of the year 1897, after which the Corporation discontinued the grant for the purpose. 573 inoculations were done from the beginning of January to the end of March.

ABSTRACT OF THE REPORT OF THE MADRAS MUNICIPALITY FOR 1897-98.

(*Colonel Sir G. M. J. Moore, C.I.E.*)

Drainage.—The drainage works at Mylapore in connection with the new drainage scheme for the city, which had been undertaken in 1896-97 were in progress, and was expected to be opened shortly. The pipes required for the Sydenham and Ice House roads were obtained during the year and the work will be commenced next year.

Water-supply.—During the year, 1,864 yards of pipes were laid and 26 fountains were erected, against 20,169 yards of pipes and 96 fountains in 1896-97. The total number of fountains at the end of the year was 1,168, being at the rate of one for every 299 inhabitants in the water-supply area. The total quantity of water supplied to the town was 479,789,325 cubic feet, exceeding that of the previous year by about 6 per cent. The quality of the water in the Red Hills Lake was again found on analysis to be "bad," still the water as distributed after filtration was pronounced "usable." Plans and estimates of a new scheme for the water-supply of the city were under preparation by the Municipal Engineer.

Vaccination.—The total number of cases vaccinated during the year 1897-98 was 33,082 against 27,021 in 1896-97, showing a large increase of 6,061 cases; and the increase was chiefly due to the prevalence of small-pox in an epidemic form during the latter part of the year under review. Out of 33,082 cases vaccinated there were 19,264 males and 13,818 females. Of the total vaccinated 30,426 were successful, 1,018 unsuccessful and 1,638 unknown. When compared with the previous year there was an increase of 474 unknown cases in 1897-98 and this was due to the large number of re-vaccinations done among prisoners of the Jails, Emigration Coolies, &c., who were released, rejected or embarked on board the ship before the result of the operation could be ascertained.

During the year 1897-98, 1,991 cases voluntarily resorted to the Vaccine Depôts for the inspection of the Vaccinator, and in 24,410 cases the results were verified by the Divisional Vaccinators under bye-law 11, and after inspection certificates of success were issued to the parents or guardians at their own houses. These results were again inspected by the Deputy Inspector and 4 Assistant Deputy Inspectors. Those cases vaccinated in the Penitentiary, Civil Debtors' Jail and Natal Emigration Depôt were verified by the Deputy Inspector. Out of a total of 33,082 cases vaccinated 14,921 cases were inspected by these Officers and the failure to verify 50 per cent. was due to the vaccine staff having been specially engaged in checking the widespread of small-pox in February and March 1898 and in bringing the unprotected under the influence of vaccination. It would appear that in those two months 8,760 cases were vaccinated, the average monthly number being 2,200 cases.

Under the revised vaccine bye-laws sanctioned by the Government and finally published in the *Fort St. George Gazette*, dated 22nd February 1898, the parents are bound to produce the vaccinated children at the Depôts for the inspection of the Vaccinators. These bye-laws were put in force from 1st April 1898.

The percentage of success in primary and re-vaccination excluding the unknown cases from the total was 96·76 against 95·96 in 1896-97 showing a small increase of ·80 per cent. due to the large number of cases vaccinated during the year in consequence of the prevalence of small-pox in the city.

Out of 33,082 cases vaccinated 1,938 were Europeans, East Indians and Native Christians, 2,781 Mahomedans, 28,355 Hindus and 8 other castes. Of the total vaccinated 24,828 were primary vaccinations against 19,193 in 1896-97 showing an increase of 5,635 cases. The percentage of success in primary vaccination was 99·56 against 99·19 in 1896-97 showing an increase of ·37 per cent. There were 8,254 re-vaccinations among adults with a percentage of success of 86·97 against 87·11 per cent. in 1896-97 showing a small decrease of ·14 per cent. As regards the high

percentage of success obtained in re-vaccination, Government in their order No. 2201 M., dated 11th October 1897, required the Health Officer to inspect 1,000 cases as a test and report on the result obtained. The late Health Officer Dr. J. Nield Cook verified 365 cases and recorded his result so far and before he could complete 1,000 cases he left Madras for Calcutta. Dr. J. W. Cornwall Health Officer, has taken up the work of inspecting 1,000 cases after entering upon his duties and the results will be reported in due course. The following statement shows the result obtained in both primary and re-vaccination :—

Year.	Primary Vaccination.				Revaccination.			
	Successful.	Percentage.	Unsuccessful.	Unknown.	Successful.	Percentage.	Unsuccessful.	Unknown.
1896-97	18,789	99·19	153	251	6,024	87·11	891	913
1897-98	24,335	99·56	106	387	6,091	86·97	912	1,251

The number of infants vaccinated under one year of age was 15,323 children against 13,129 in the previous year showing a large increase of 2,194 cases with a percentage of 99·70 of success against 99·36 in 1896–97. Among children above one and under six years the number vaccinated was 8,771, and among those above six years 8,988 were vaccinated.

Vital Statistics.

Births.—The total number of live-births registered during the year 1897, amounted to 18,702 against 18,684 in 1896 showing a small increase of 18. The ratio per 1,000 per annum calculated on the census population of 1891 was 41·3 against 41·2 of the previous year. This increase though very small must be viewed with satisfaction, considering the distress induced by famine which was felt in the town as well as in the Presidency. The birth-rate of a population being directly influenced by its prosperity and adversity, it would not have been surprising if a considerable reduction in the birth-rate had occurred. The number of still-births registered during the year 1897 amounted to 410 being 2·2 still-births to 100 live-births. The ratio is unquestionably too low for a city like Madras and it can only be explained by the fact that a number of still-births are not recorded as such or that such births are entirely concealed. The latter seems the more probable of the two, seeing that the Hindus have a prejudice against burying their first-born in a public burial ground. The male births numbered 9,422 and the female 9,280, giving a proportion of 101·5 of males to 100 of females.

According to caste the birth-rate among the Mahomedans was 43·1 per 1,000, among the Hindus 41·6, and among the Christians 36·2.

Mortality.—During the year 1897 there were 16,086 deaths registered in Madras, giving a death-rate of 35·5 per 1,000 calculated on the census population of 1891, against 17,131 or a ratio of 37·8 in the previous year, the average for the decade being 17,987·5. Of the 16,086 deaths registered, 7,953 occurred among males and 8,133 among females, giving a proportion of 97·7 to 100.

The number of deaths according to nationality was Europeans 108, Eurasians 366, Native Christians 709, Hindus 12,833, Mahomedans 2,062, and others 8. The ratios per 1,000 are 29·7 among Christians, 35·7 among Hindus, 38·7 among Mahomedans and 13·4 among "others" against 31·2, 37·9, 42·5 and 13·4 of the previous year.

There was a decided fall in the number of death from Fevers during the year under report from 6,039 in 1896 to 5,484 in 1897. A like fall also occurred in Measles and Diarrhœa and Dysentery from 494 to 410 and 2,353 to 2,000. But the mortality from Small-pox rose from 42 to 114, highest since 1884, and that from Cholera from 97 to 169, highest since 1892.

Small-pox and measures adopted for its prevention.—The total number of deaths registered in 1897 from small-pox was 114 against 42 of the previous year and the number of attacks reported in 1897 was 238. The small-pox of 1897 was a

continuation of that which commenced in the beginning of 1896. The incidence on the vaccinated and unvaccinated is shown in the following table :—

—	Attacks.	Deaths.	Fatality.
Unvaccinated	149	91	61·0
Said to be vaccinated but no marks ...	44	13	29·5
Vaccinated	44	10	22·7
Had previous attack of small-pox ...	1	—	—
Total ...	238	114	47·9

—	Total deaths.	Under 10 years.	10–20.	Over 20.
Unvaccinated... ...	91	82	6	3
Vaccinated	10	5	1	4

The tables clearly indicate the protective influence of a single vaccination so far as the mortality amongst the attacked is concerned :—Vaccination was vigorously pushed in infected localities, house to house inspections were made and the unprotected were vaccinated. Re-vaccination was encouraged in public institutions. Sanitary Overseers promptly disinfected the houses of the Small-pox cases and destroyed the bedding and clothes of the patients. Endeavours were made to isolate patients who had insufficient accommodation in their houses in Small-pox Hospitals.

Cholera.—The mortality from Cholera was above the average of the previous 4 years. The number of deaths registered was 169 against 97 of 1896 and 80·75 the average of the four previous years. The mortality from cholera was as usual greatest in 1st Division where alone 59 deaths occurred, giving a ratio of 0·8 per 1,000. Of the 169 deaths, 36 occurred in the 1st quarter, 5 in the second, 96 in the third and 32 in the fourth. The increase in the number of deaths in the third quarter appears to have been due to the importation of the disease from Periapalayam and Conjeeveram into the city.

During the year two deaths occurred from plague—the first case was imported from Poona, and the second was the result of direct inoculation from the first at the post-mortem. A full history of these cases is given under Plague Prevention.

Measles.—The number of deaths registered from measles was 410 against 494 of the previous year, but it was considerably above that of 1894 and 1895 when only 190 and 249 deaths were registered.

Fevers.—Excluding other causes by far the largest number of deaths is recorded as due to Fevers. The number of registered deaths attributed to Fevers in 1897 was 5,484 or 555 deaths less than the previous year. As in the previous years, the highest number of deaths from fevers, 1,158 was recorded in the 1st Division, with a death-rate of 16·1 from fevers alone. Until adequate provision is made, for effective drainage the proper disposal of dead bodies and refuse of all kinds, the supply of wholesome water and other sanitary requirements of prime importance, any great reduction in the fever death-rate cannot be expected.

Bowel Complaints.—Under the heads of Dysentery and Diarrhœa there were 1,496 and 504 deaths registered in 1897 against 1,721 and 632 of 1896. There was a steady fall under this head since 1892.

Infantile Mortality.—There was a decided fall in the rate of infantile mortality during the year under report, from 407 deaths to every 1,000 births of 1896 to 369·6, deaths to every 1,000 births of 1897. This though gratifying is still very high compared to the rate in British towns. This can only be accounted for by the general ignorance of the masses in matters relating to management of birth and infancy coupled with the existence of insanitary conditions and aggregation in most parts of the town. The total number of deaths for the year registered under this head was 5,052 against 5,570 of last year.

Plague Prevention.—As in last year, so in the year under report the precautionary measures adopted against this disease have formed an important feature of the administration. In addition to the staff consisting of 1 Hospital Assistant, 1 Special Sanitary Inspector, 2 Overseers and 2 Peons maintained last year, 4 additional men were engaged under the name of " Plague men " to be sent with persons who give no clear addresses at the platforms to find out their exact residences. As the huts in paracheries have no door numbers such a procedure was found to be necessary. The usual procedure of observing for ten days all the arrivals from outside the Presidency was continued. Eight Hospital Assistants were entertained during the year with a view to examine dead bodies at burial grounds to find out the causes of deaths that occur daily in the city. This was found to be impracticable, as such a procedure cannot be undertaken without special legislation on the point empowering the medical men to demand examination of dead bodies. Their services were in consequence utilized in times of cholera and small-pox by deputing them to generally assist the Sanitary Inspectors in adopting the preventive measures to the spread of these diseases. The Royapuram Regimental Hospital and Egmore Women and Children's Hospital were fitted up to receive and treat cases of plague if any occur.

During the year a case of plague was imported into the city from Poona. The syce of a gentleman, who returned to Madras after Poona races, was taken ill with fever on the third day of his arrival and he was removed at once to the General Hospital where the case was diagnosed to be one of plague. On the receipt of this information the building where the patient lived previous to his removal to the hospital was vacated and was thoroughly disinfected. All the occupants of the house were removed to the segregation camp and observed for ten days.

Unfortunately continuing upon this case another fatal case occurred from direct inoculation at the post-mortem. This was one of the toties of the General Hospital. The residence of this toty—a hut in Pudupet hutting ground, was burnt down and fenced round and the occupants of the hut were segregated and observed. A probationary Overseer and the Assistant Health Officer inspected the hutting ground for 10 days making house to house visitations to find out if any new cases occurred.

ABSTRACT OF THE REPORT OF THE MUNICIPAL COMMISSIONER FOR THE CITY OF BOMBAY FOR 1897-98.

(*W. L. Harvey, Esq., Acting Municipal Commissioner.*)

SPECIAL DRAINAGE.—*Unfinished Works.*—The progress of these is described below, the names of the works being printed in italics. The *Colaba Sewerage Works* were completed at a total cost of Rs. 8,21,010, only Rs. 3,848 being spent in the year of report. On the *Umarkhadi Sewerage Works*, which were also completed, Rs. 61,871 were expended in the year, bringing up the total expenditure to Rs. 3,52,239. The *Parel Sewerage Works* (*gravitation portion*) were completed at a total cost of Rs. 62,081. The *Mazagon Sewerage Works* (*gravitation portion*) were very near completion, the total amount expended on them being Rs. 2,55,569 out of the sanctioned grant of Rs. 3,32,661. The *Malabar Hill and Khamballa Hill Sewerage Works* (*gravitation portion*) were practically completed in January 1897, and the final accounts were certified and passed in September 1897 at Rs. 1,08,552 for the total cost. The amount spent on *House Drainage Connections* (*street portions*) *in the Colaba District* was Rs. 6,866 on making 189 connections. *The Fergusson Road and Chinchpoogly Sewerage Works* were completed at a cost of Rs. 85,361, and the work of *Draining Stormwater from roads around Mahaluxmi Dhobiwada* at a cost of Rs. 1,156. The laying of a *9-inch pipe drain for the carriage of storm-water to the sea from the southern part of Wodehouse Road* cost Rs. 1,992. A *12-inch Stoneware Pipe Sewer from the Emergent Reservoir at the Wellington Fountain to the Manhole in Apollo Street opposite the Dockyard* was laid at a cost of Rs. 3,189.

New Works.—Among the principal works completed were:—The Old Race Course sewerage works (gravitation portion); the improvement of roadside drains and provision of water gullies in the Khetwadi District; avoiding side drains in Girgam Road and Pathan Street; storm-water drains in Rampart Row, Wodehouse Road, Lower Colaba Road, Thomas Street, and the eastern foot of Wodehouse Bridge; and an arched masonry drain between Gilder Lane and the B. B. & C. I. Railway. The principal new works which were still in progress at the end of the year are:—A masonry drain from Girgam to Back Bay; a storm-water drain from the Wellington Fountain to the sea; and the improvement of roadside drains and watercourses in and about Dadar Road.

Other Drainage Works.—Arrangements were made during the year for starting the following important works sanctioned by the Corporation, the first of which is expected to be completed by the 31st March 1900:—Machinery for the sewerage of the Parel, the Old Race Course, the Malabar Hill and Khambala Hill, the Elphinstone Reclamation and the Fergusson Road and Chinchpoogli Sectional Districts (on Shone system, Rs. 8,77,625; Mazagon District (sectional), Rs. 3,30,072.

The Colaba Air Compressor Station.—This station and the ejector stations working in connection therewith worked satisfactorily during the year without any serious stoppage or breakdown.

DRAINAGE.—*The Love Grove Pumping Station* was maintained in a state of efficiency throughout the year at a total cost of Rs. 88,026-5-9, the Worthington engines continuing to give satisfaction. The station enjoyed complete immunity from plague in spite of some of the men frequently coming into contact with the sewage which might be supposed to contain active bacilli.

House drainage connections.—The existing house-connections of 98 premises in Mandvi District were put into proper working order at the expense of the house-owners. The drainage fittings of 107 houses in Mandvi and 259 other houses in other localities in which plague cases had occurred were treated at a cost to the owners of Rs. 50,059-0-6. The house drainage connections of 27 houses in Kalachowki Road were made at the house-owner's expense. In 43 other houses in various parts of the City the sanitary arrangements were remodelled. Besides the street portions of house drainage connections in Colaba executed by the Special Drainage Department, 614 connections were made in various parts of the City at a total cost of Rs. 44,390.

Electrolized Sea-water.—The plant for providing electrolized sea-water put up in 1896–97 at Carnac Bunder night-soil depôt at a cost of Rs. 23,800 was worked during some portion of the year of report, but without any decisive results, the Executive Engineer not being yet in a position to state conclusively how the fluid produced compares in efficiency and cost with other disinfectants. The cost of working and maintaining the plant up to the end of the year was Rs. 1,135.

WATERWORKS.—*Tansa Lake.*—The rainfall for the year was 104·82 inches, against 120·13 and 92·37 inches in 1896 and 1895 respectively. The heaviest fall was on the 7th August, when 7·95 inches were registered. The lowest water level was 393·19 T. H. D. on the 17th June 1897. The lake overflowed on the 18th July 1897 after 35·38 inches of rain had been registered, and ceased to overflow on the 24th September 1897. The storage above lowest outlet on the 1st October 1897 was 18,559 millions of gallons, and on the 31st March 1898 it was 12,396 millions of gallons, showing a consumption of 6,163 millions of gallons in six months, or 34·05 millions of gallons per day, including evaporation, absorption and leakage. The quantity of water passed over the waste weir is estimated at 26,403 millions of gallons. The approximate quantity of water passed from the duct at the Ghatkoper syphon head for the year amounted to 7,275 millions of gallons. About 213 millions of gallons of water passed into the Vehar Lake against 165 and 88 millions of gallons during 1896–97 and 1895–96 respectively. The daily average of the quantity supplied to the City and delivered into Vehar was consequently about 20½ millions of gallons a day, leaving about 13½ millions a day for leakage, absorption and evaporation in the lake and the duct.

A sum of Rs. 62,115 was sanctioned for repairs to the portion of the embankment from Godowli to the north of the Bassein creek No. 3, and a greater part of it was completed by the end of the official year.

Vehar Lake.—The rainfall for 1897 was 97·56 inches, against 109·81 and 82·81 inches for 1896 and 1895 respectively. The lake overflowed on the 8th August 1897, and ceased to do so on the 7th October 1897. The heaviest fall was 7·56 inches on the 16th July. The lowest water-level was 251·71 T. H. D. on the 16th June 1897. The storage on the 1st October 1897 was 11,425 million gallons ; on the 31st March 1898, 8906 million gallons ; the total consumption of water from the lake during the dry months from 1st October 1897 to 31st March 1898 was 2,519 million gallons, equivalent to 13·9 million gallons per day in addition to 213 million gallons drawn from Tansa. Between the 7th August and 8th October 1897, 1,098 million gallons of water were received from Tulsi Lake by overflow. The quantity that passed over the Vehar waste weir between the 8th August and 7th October was 4,287 millions of gallons.

Tulsi Lake.—The rainfall of 1897 was 118·66 inches, as compared with the previous two years, 1896 and 1895, when it was 139·52 and 100·40 inches respectively. The heaviest fall was on the 8th August 1897, being 7·76 inches. The lowest water level was 435·00 T. H. D. on the 17th June 1897. The lake overflowed on the 7th August 1897, and ceased to overflow on the 9th October 1897. The storage on 1st October 1897 was 2,305·6 million gallons ; on the 31st March 1898 it was 1,304 millions. The total volume of water drawn from the lake during the six dry months from the 1st October 1897 to 31st March 1898 was 1,001 million gallons, or 5·5 million gallons per day, allowing 4½ millions for supply and leaving about 1 million for leakage and evaporation.

Pawai Lake.—The water supply from this lake was not required. The pumping plant remained in charge of the Assistant Engineer, Mechanical Branch.

Bhandarwada Reservoir.—The expenditure for the work of covering storage basin and construction of filters over it during the year was Rs. 1,23,084–7–4. The work of pointing the four walls and paving the floor of the storage reservoir with Indian patent stone was completed by Messrs. Garlic & Co., at a cost of Rs. 23,086–0–9.

Malabar Hill Reservoir.—Filters Nos. 2, 3 and 4 have had some alterations made in their outlet arrangements and are now in process of being recharged with filtering materials.

Distribution and maintenance.—A large quantity of water was used during the year under report, also for flushing the drains and gutters on account of the prevalence of plague, and 327 house-connections were cut off and replaced by 246 stand-pipes in convenient positions. The number of bursts during the year was 109 against 180 last year and 255 in 1895–96. Exclusive of the connections cut off on account of the plague,

365 services were disconnected on account of demolition of buildings, non-payment of rates, &c. There were 2,209 meters in use on the 31st March 1898, being an increase of 162. The consumption registered by meter aggregated a little over 1,253 million gallons.

Public Health.

The state of the public health during the year under review was very unsatisfactory. The mortality was 14,445 more than in the preceding year. The total number of deaths from all causes amounted to 47,896, equal to a death-rate of 58·28 per 1,000 of population, calculated on a population of 821,764 (census of 1891). The average number of deaths for the previous five years amounted to 28,609, or a death-rate of 34·81 per 1,000 of population.

The number of deaths according to place of birth was as follows :—

Born in Bombay	16,191
Born elsewhere and unknown	31,705

Cholera.—The number of deaths from cholera was 1,265, being 775 more than in the preceding year. The sections of the greatest mortality were Byculla, Tarwady, Parel, Mahim, Worlee, 1st Nagpada, Middle and Lower Colaba, being 3·50, 3·33, 3·13, 2·97, 2·74, 2·60 and 2·42 per 1,000 of population. The highest death-rate by caste was amongst Hindu low-castes, Native Christians, Lingaets, Brahmins, Jains, Mussalmans and Jews.

Small-pox.—The deaths from small-pox were 57, being 644 less than in the preceding year. The rate of mortality was highest amongst Hindu low-castes and Mussalmans. The mortality was highest in 1st Nagpada, Kamathipura, 2nd Nagpada and Byculla.

Measles.—There were 359 deaths from measles, being 118 more than in the last year. Of these, 274 occurred in the first four years of life. The highest mortality was amongst Hindu low-castes and Mussalmans. The death-rate was highest in 2nd Nagpada, Byculla, Tardeo, Kumbharwada, Khara Talao and Kamathipura.

Fevers.—There were 6,951 deaths from fevers, being 1,825 less than in the last year. The death-rate was highest in the districts of Parel, Sewree, Kamathipura, 2nd Nagpada, Byculla, Tardeo and Mahim. The greatest mortality was amongst Negro-Africans, Hindu low-castes, Budhists, Mussalmans, Lingaets and Hindus of other castes.

Leprosy.—There were 63 deaths from leprosy, being 9 more than in the preceding year.

Plague.—There were 11,003 deaths from Plague. Detailed particulars of this disease have been given by the Executive Health Officer in his report.

Births.—The number of births registered, exclusive of still-born, was 9,336, or 6,554 less than in the last year. Of these, 4,903 were males and 4,433 females. The diminution in the number of births was probably due to the exodus of people on account of the prevalence of the plague. Excluding Negro-Africans, the birth-rate was highest amongst Hindu low-castes, Jews, Parsees and Eurasians. The sections giving the highest birth-rate were Mahim, Byculla, Upper Colaba, 2nd Nagpada, Khetwady, Fort Northern, Tardeo, 1st Nagpada, Mazagon and Worlee.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF BOMBAY CITY FOR 1897.

(*Brigade-Surgeon-Lieutenant-Colonel T. S. Weir.*)

Before examining the mortality, it is well to consider the position of Bombay. The portion of Bombay in which most of the population live in closely built houses and densely populated habitations lies in a valley between rocky ridges, the centre of the valley in places lying below mean sea level; on the south side most open to the sea, and raised above the sea level by sand and alluvial deposits. Up the valley, in between hillocks, at one time flowed creeks. These creeks and the hollows have been largely filled with vegetable matters which have not at depths yet decomposed. There is still underground an ooze, where these creeks flowed, and the ground waters of the valley are influenced by the pressure of the sea currents around.

The valley of Bombay is most unfavourably situated. Into it flows the rain water from higher lands, the escape of which is obstructed by roadways and buildings, and to the north by a dense clay formation. But happily the soil has a marvellous power of purification, even greater than the air. In the centre of the valley to which most of the drainage flows, the soil is a stiff clay.

The area of Bombay is about 22 square miles, and on a portion of this area there is the most densely crowded population in the British Empire, the six sections of greatest density of population having 227,021 people on an area of 403·28 acres.

The following table shows the sections of the greatest density and their populations :—

	Population.	Area.	Persons to an acre.
Khara Talao	27,035	40·33	670·39
Chukla	32,197	51·23	628·47
Kumbharwada	32,209	52·23	616·67
Market	44,751	83·63	535·10
Bhuleshwar	38,363	71·73	534·82
Umarkhadi	52,466	104·13	503·85
	227,021	403·28	—

In 1895, before the appearance of Plague, Bombay was more healthy than any large city in India, and the chances of life were better than in many European towns. I need not do more than refer to the high mortality in Bombay one hundred years ago, when residence in it was regarded with apprehension.

It is forgotten that this city has grown so rapidly that all the improvements that other cities have had centuries to complete are not to be accomplised in Bombay in a few years. Few people realise the enormous improvements that have been effected in the last twenty years, whether it is in the highways, or in the habitations of the people, or in the reclamation and improvement of the surface ground.

The course of the epidemic of Plague is marked out in the diagram (not reproduced) of the mortality from day to day, and it may be divided into five periods of five epidemics, so to speak—

I. Commencing on the 19th September 1896 and ending about the 15th of October.

II. Commencing after the 15th of October and ending about the 4th of November.

III. Commencing after the 4th of November and, after a series of repressions, developing into the great epidemic which culminated in a high mortality on the 28th of December, and reached its greatest intensity and virulence about the 15th of January 1897.

IV. Commencing in the second week of July 1897, and reaching its maximum in the second week of August, and declining till it reached its minimum in the middle of November.

V. Commencing in the second week of December 1897, and gradually developing into the great epidemic of 1897, with slighter repressions than in the previous year, till, on the 9th of February 1898, a mortality of 347 was reached, followed by a series of repressions and fluctuations, till on the 16th of March the mortality rose to 358, and again on the 18th to the same number, from which period the mortality commenced to decline in irregular curves.

Such has been the progress of the pestilence since 1896.

There are good reasons for thinking that the epidemic might have reached its fastigium on the 9th of February 1898 if the measures, as was found advisible a month later, had been relaxed. If the concealment of cases had been less, the epidemic would have decreased sooner was the belief I expressed. An epidemic can be irritated as well as a local sore, and the period between the 9th of February and the 15th of March may be described as the period of panic and irritation. The measures were followed by the concealment of cases, and concealment led to the intensification of the type. The conditions existed which it would have been necessary to create had it been desired to intensify the disease.

Though the number of Plague cases was less than in 1896, the total mortality was higher. This implied concealment of the disease and intensification of the type through concealment. There is no better tribute to the work of the Health Department in 1896 than that in 1897, with a higher mortality, with an enormously greater expenditure, and with a vast organization—fewer cases of plague were at that period detected by the Plague Committee than by the Health Department in 1896. I admit the difficulties of the Plague Committee. The population was against them, and they had lost the assistance of the medical profession. It was difficult for them to obtain information, for the people did not call in medical men.

The view I took was this, that the future depended on—

(*a*) the multiplication of the rat population ;
(*b*) the disappearance of the disease from amongst rats ;
(*c*) the susceptibility of the human population.

Till the rats become immune, the disease must continue to occur amongst human beings wherever it has been epidemic.

In my last report I pointed out that all who came to study the disease in this city were surprised that the mortality was so low. The mortality in Bombay, having been much lower than in any place outside Bombay, deceived no doubt a great many people, and gave them an utterly wrong idea of the value of the measures being taken. They were buoyed up with a hope that it was only necessary to carry out certain measures and display various activities and the epidemic would be stayed. The pest would not be called plague if it was so easily to be defeated. This disease is concurrently epidemic amongst human beings and animals. The importance of this fact even those who came here to advise us did not comprehend—that from the earliest times far more drastic measures than have been adopted or suggested in India have been applied against the pest and have always failed to stop its progress. Until recently there was the most extraordinary ignorance as to the measures taken in ancient times to prevent the development and spread of plague.

Even in 1897, with the second recrudescence or epidemic of plague, followed by a third recrudescence, the total mortality from all causes in Bombay was not as high as the

mortality from plague alone in many places in India. In 1896 the total mortality (including plague and all other diseases) was only 40·71 per 1,000, and in 1897 it was not higher than 58 per 1,000. In places where plague has been epidemic, the mortality from this one cause has not infrequently been higher than the mortality from all causes in Bombay.

The highest mortality in Bombay from plague occurred in the suburbs, in the districts of—

——	No. of Deaths.	Death-rate.
Mahim	666	35·99
Sion	460	23·46
Kamathipura ...	619	21·19
Parel	603	20·98
Sewri	122	20·12
Byculla	919	19·38

OF THE BOMBAY BRANCH OF THE

Cholera was but *one* of the disease causes contributing to the high mortality after June. The recognition of the types of diseases at that period was, in the opinion of experienced medical men, often attended with great difficulty. If the recognition of the type was difficult, correct registration could not be hoped for in this City, where only a small proportion of those who succumb to disease are attended in this last illness by medical men. The people—the mass of the population—had almost ceased to call in medical men when they suffered from fever. This was the most serious aspect of the effect of the measures being adopted to detect cases of plague.

In estimating the distribution of the mortality from plague by class, it has to be remembered that the mortality in some classes cannot be accepted as correct. Not only has concealment of cases to be calculated on, but imperfect recognition of the disease. The lowest mortality occurred amongst *Europeans*—20 deaths were registered. As far as the European mortality is concerned, it may be taken as correct. The mortality from plague amongst Europeans raised slightly the total death-rate in the community. The next lowest mortality occurred amongst *Musalman*—5·4 per 1,000. This cannot be accepted as correct, though the Musalman population suffered *less* than many other classes. Apart altogether from concealment, there is a margin that must be left for imperfect recognition of the disease, as only a small proportion of the Musalman sick were attended by medical men. The mortality amongst *Jews* was as low as 5·9 per 1,000. *Bhattias* had a registered mortality of only 7 per 1,000, but this cannot be considered as correct, though Bhattias did not suffer so much as other allied communities. The mortality of *Brahmins* is also low, but the total mortality in the Brahmin population is only 38 per 1,000 ; evidently a large number of cases of plague amongst Brahmins did not escape detection. It is remarkable this low mortality amongst Brahmins. Amongst *Eurasians*, allowance has also to be made for imperfect recognition of the disease. The highest mortality occurred in the *Hindu low-caste* population, and also probably the least recognition of cases.

If we take the *Parsee* community, the Plague mortality was 7·52 per 1,000. If this is deducted from the total mortality, it gives a mortality of 25, so that the increase in the mortality of the Parsee community is very nearly accounted for by the mortality from Plague. There could not, as would be expected, have been any great concealment of cases.

Up to the commencement of the work of the Plague Committee on the 1st of April, the difficulty, I would again repeat, was to obtain recognition of the disease, to secure correct diagnosis.

If we take the principal classes, in only one, namely, Europeans, is the mortality from all causes less than in 1896. The enhancement varies from 4.51 amongst Parsees to 19·76 amongst Musalmans.

Notwithstanding the high mortality of the year, the European mortality is lower than in many previous years, as will be seen from a table following. This is remarkable. The low mortality in the European population is very remarkable, for Europeans not only did not flee the City at any time, but many of them approached the disease, and exposed themselves to contagion in aid of the sick.

The mortality by *class* has fluctuated between 23·9 per 1,000 amongst Hindu low-caste, 5·4 amongst Musalman, and 1·7 per 1,000 amongst Europeans.

TABLE SHOWING THE NUMBER OF DEATHS AND THE DEATH-RATE FROM PLAGUE BY CLASSES IN 1897.

CLASSES.	Population by Census of 1891.	Number of Deaths.	Death rate per 1,000 of Population.
Jains	25,225	373	14·78
Brahmins	37,982	397	10·45
Lingaets	784	26	33·16
Bhattias	7,891	59	7·47
Hindus of other castes ...	451,465	7,172	15·88
Hindus, low-caste	45,169	1,084	23·99
Musalman	155,101	846	5·45
Parsees	47,458	357	7·52
Jews	5,021	30	5·97
Native Christians	29,712	580	19·52
Eurasians	4,330	42	9·69
Europeans	11,290	20	1·77
Negro-Africans	146	4	27·39
Buddhists	190	—	—
Other and Unknown castes...	—	13	—
Total	821,764	11,003	13·39

The mortality by *habitations* indicates the influence of ventilation in giving protection against the disease, for it has generally been lowest in the highest rooms of the highest buildings.

The distribution of mortality by *districts* discloses an extraordinarily low mortality in one district—the Fort, South. In this district in 1896 the total mortality from all causes did not exceed 5·31, and in 1897 it was not more than 8·85 ; and yet round this district a cordon was not placed, nor were any measures taken that were not carried out in other districts.

The recurrence of the disease by *houses* is most interesting. In those buildings from which the downtake pipes were removed and disinfected, and, if they were imperfect, replaced, and open drains constructed in the house gullies properly connected to the sewers, the disease has not greatly revived. I take two buildings, both on Mandvi Bunder. In one building in 1896, 19 cases occurred, in the following year 7 cases, and in 1898 2 cases. I take another building on the other side of the bridge. In 1896 as many as 17 cases occurred, in 1897 only 2, and in 1898 but 1.

The mortality from Plague by sex and age indicates that the disease has been *most* fatal to *males*, and most fatal *after* adolescence had been reached. In both sexes there is a remarkable ascent in the mortality about the 10th year of age. Amongst males the most fatal period was between 35 and 40 years of age, and amongst females in the early years of puberty and later life. It may be said that under five years of age the recognition of the disease is more difficult and the malady more rapidly fatal than at advanced periods. Hence the *true* mortality in childhood is *not* known, nor the incidence of the disease at different periods of life indicated by the statistics.

The mortality was highest with the greatest intensity of the disease towards the end of January and the beginning of February. The number of cases decreased through March, April, May and June, till the minimum of 42 was reached in July. From the middle of July the mortality commenced to increase, and continued with fluctuations to increase till the end of the year, rapidly rising in December into an epidemic fatality.

The proportion of deaths to cases by dwellings is most interesting.

TABLE SHOWING THE PROPORTION OF DEATHS TO ATTACKS FROM PLAGUE IN ALL WARDS AND THE WATER DIVISION, FROM JANUARY TO DECEMBER 1897.

Wards.	Ground Floor.	First Floor.	Second Floor.	Third Floor.	Fourth Floor.	Fifth Floor.	Harbour.	Road side.	Unknown.	Total.
A	72·2	65·8	70·4	57·1	53·8	54·5	66·6	58·6	—	67·8
B	71·1	68·6	59·9	58·9	47·7	33·3	66·6	68·4	—	65·7
C	80·3	78·7	64·8	57·7	42·1	33·3	—	66·6	—	75·6
D	84·7	74·3	58·9	64·2	33·3	—	—	63·1	—	81·5
E	87·5	80·0	77·2	66·6	50·0	40·0	—	50·0	—	84·0
F	92·0	77·7	66·6	100·0	—	—	—	93·3	—	90·8
G	83·6	63·8	63·6	50·0	—	—	—	80·0	—	82·3
Unknown	—	—	—	—	—	—	—	—	100·0	100·0
Water Division ...	—	—	—	—	—	—	100·0	—	—	100·0
Total ...	84·7	75·5	67·3	59·7	48·1	45·4	84·6	62·2	100·0	82·6
Total last year	74·7	79·0	76·5	66·1	59·0	66·6	—	96·3 85·1		76·1

This mortality in dwellings illustrates the influence of ventilation on the disease.

The chances of recovery progressively increased from the *first* floor upwards ; from 84 per cent. on the ground floor to 45 per cent. on the fifth floor the mortality decreased ; and even the people picked up on the road side, destitute though they may have been, had a better chance of recovery than those living on the ground floor. The proportion of mortality to the height of residence indicates the great influence of exposure to the air in preventing the spread of the disease. It will be observed that in *all* the wards there is the same progressive decrease in the fatality with the height of buildings.

It is an interesting fact that the number of persons found on the road-sides decreased progressively from January up to December, in which month, with the development of the epidemic, the number commenced to increase.

In another portion of this report I have referred to the influence of house-drainage in preventing the recrudescence of plague. At first I thought the effect of drainage was due to the improvement of the general sanitary condition of buildings, but I have now come to the conclusion that it is dependent on the closing of rat-holes and the demolition of the homes of the rats. When plague recurs frequently, it is, I believe, due to there being favourable hiding and feeding places for the animals. If it were practicable through any public agency to carry out house-drainage, to remove and clean all down-take pipes, to construct and repair all house drains and gullies, it would have a great influence on the recrudescence of plague.

It is a remarkable fact that the highest mortality from plague occurred in the sections to the north and south of the Island. To the north the highest mortality occurred in the sections north of a line running through Grant Road, and to the south in the suburbs of Colaba. A lower mortality occurred from plague in the surface crowded portions of the City than in the suburbs. The explanation, I believe, is ventilation ; the chawls in which the poor classes live have often a gully on one side, and into this gully windows open. In consequence of this there is more air circulation in the rooms in which they live even in chawls than in the central and dark rooms in the old-shaped buildings in the suburbs, although these buildings may be in the fields or surrounded by open spaces.

The knowledge that rats are carriers of the disease is widespread, and is now being practically made use of by people who never had cats before, but who now keep and feed cats. (In the houses of people who never kept cats before, cats may now be seen, and even people who had a dislike to the animals may now be seen putting out food for them).

The experience of last year has been repeated. Cases have generally been preceded by the disease among rats.

Dr. Gimi, in a note on the mortality amongst rats preceding cases of plague, states that about the middle of January 1898, in Popatwadi, Girgaum Road, and Marine Street, dead and dying rats, were found, and that cases of plague occurred a few days afterwards. He also noticed that up to the above date the mortality in Dhobi Talao Section ranged from 3 to 5 deaths a day (including one or two deaths from plague), but within a *week* after the appearance of sick rats, the cases of plague increased from 8 to 13 a day for a week.

Dr. Godinho also submitted a note on the infection from rats, their routes of migration, and the mortality following on their appearance in houses in Dukargally, chiefly Burrow's Lane and Khoja Street, during January, February and March 1898. His observations showed that the rats travelled from south to north and from east to west, seldom or ever the contrary points, and that they infected one side of a street first, and then the other, before departure.

In the report on plague in 1896 I held that the treatment of the sick might be modified according to (*a*) the type of the disease, and (*b*) the ventilation of buildings. I believe the correctness of this view has been established by experience. I can see no reason why patients ill from plague should not be treated inside the verandahs of buildings when the verandahs are wide and look on to open spaces ; *or why in the fair weather, when there is open space outside buildings, awnings should not be put up and patients allowed to be placed under them.* There is no use in evading the fact that the patients would be better placed for themselves and of no more danger to others under these conditions than in many private hospitals.

I have contended since 1896 that every effort should be made to encourage the people to submit to inoculation with Mr. Haffkine's prophylactic serum, and that measures should be taken to make use of inoculation against plague in the same way as measures are adopted to carry out vaccination against small-pox.

There was before the end of the year serum ready for 100,000 people, and I was strongly of opinion that while all the sanitary measures, adopted from the beginning, should continue to be enforced, inoculation should be used as an additional weapon to protect the population. It is a weapon ready to hand and should be used with every other weapon at hand to resist the pest. Such was my opinion. The sole encouragement of inoculation has from the first come from the municipality—the credit of supporting it when it was discouraged is due to us.

It will be observed that the mortality in the two Municipal Hospitals was almost the same. In Grant Road Hospital the percentage of deaths to cases was 67·4, and in Arthur Road Hospital the mortality was 67·87 per cent. The average mortality to be expected amongst the Hindu population generally, under the most favourable conditions of treatment, may be taken at about these results. Amongst some classes, as Europeans, the mortality may be lower ; for instance, in the European General Hospital the mortality was 35·2.

When the mortality from all causes is examined in the large and important classes of population, living more or less together, it will be observed that it is highest amongst Hindoo low-class, as this group of communities is classified ; being as much as 103 per 1,000. In one class, namely Europeans, it is normal. After Europeans the mortality ascends through the Parsee and Brahmin communities, and reaches 42 per 1,000 amongst Eurasians and 44 per 1,000 amongst Jews. Jews are therefore in this city more susceptible to this and other diseases than Europeans. The cause is simply this—there is a large number of very poor Jews in Bombay and a large immigration of destitute Jews every year.

The mortality by *months* shows that the plague epidemic had commenced to *wane* in January. In that month 7,518 deaths were registered ; in February the mortality fell to 6,860, and continued to fall till the minimum mortality was reached in June. In July the mortality rose to 2,989, and in August it ascended still higher, for 3,924 deaths were registered. Through September, October and November the mortality decreased, till in November 2,840 deaths were registered ; but in December, when the recrudescence assumed an epidemic character, there was a great rise in the mortality, and as many as 3,615 deaths were registered in this month.

There were, therefore, *three* distinct periods of epidemic intensity during the year :—1, in January ; 2, in August ; 3, in December.

STATEMENT SHOWING THE NUMBER OF DEATHS FROM ALL CAUSES BY MONTHS IN 1896 AND 1897.

Months.	No. of Deaths from all causes exclusive of still-born, in 1896.	No. of Deaths from all causes, exclusive of still-born, in 1897.
January	2,171	7,518
February	2,253	6,860
March	2,534	5,336
April	2,565	3,528
May	2,427	2,353
June	2,029	2,208
July	2,299	2,989
August	2,669	3,924
September	2,616	3,476
October	2,868	3,249
November	2,889	2,840
December	6,131	3,615
Total	33,451	47,896

The incidence of the mortality by place of birth shows that during this year of pestilence the people born *in* Bombay suffered much *less* than strangers. While the deaths amongst people born in Bombay were only 2,554 more than in 1896, the mortality among strangers was as much as 10,997 higher than in that year. The average number of deaths among people born in Bombay is 12,607, and amongst strangers 12,924. It will therefore be seen that the mortality in this year, if classified according to place of birth, is in *excess* of the average by 3,584 deaths among persons born in Bombay, and 17,655 *deaths among strangers.* In short, the mortality amongst strangers has been more than *double.* The reason of the lower mortality amongst the population born in Bombay is, as in the case of Europeans, better dwellings.

The influence of the plague epidemic on the health of people born in Bombay is well shown in the incidence of the mortality by months. The mortality among people born in Bombay rose in January to 2,497, and fell in May and June to the normal level. The recrudescence in July and August is shown in the higher mortality amongst people born in Bombay in these months ; but after August the mortality till December did *not* rise much amongst them.

The highest mortality from any one death cause is referred to plague, being 13·3 per 1,000. The three chief death causes that contributed to the high mortality are :—1, plague ; 2, diseases of the respiratory system ; 3, fevers.

TABLE SHOWING THE NUMBER OF DEATHS AND THE DEATH-RATE FROM THE PRINCIPAL CAUSES DURING 1897.

Cause of Death.	No. of Deaths.	Death-rate per 1,000 of population.
Small-pox	57	·07
Measles	359	·44
Fevers	6,951	8·46
Cholera	1,265	1·54
Phthisis	5,927	7·21
Plague	11,003	13·39
Diseases of the Nervous System	2,141	2·60
Do. do. Respiratory System	7,857	9·56
Diarrhœa	1,869	2·27
Dysentery	1,682	2·05
Accidents	520	·63
Other and unknown causes	8,265	10·06
Total	47,896	58·28

Amongst death causes that contributed to increase the mortality, it will be observed, are deaths from old age or debility; 3,206 deaths were referred to these causes, being as many as 782 above the average.

In a year when the calamity of pestilence fell on a population already tried by famine, and the thoughts of the people were to escape the dread scourge, it might have been hoped that fewer human beings would give thought to destroying one another, or to injuring themselves; and it might have been expected that fewer persons would have endangered their own lives or undertaken enterprises of risk. And it was so in one respect, for the deaths due to poisoning are 23 below the average; but the deaths due to injuries are 107 above the average.

It is a suggestive fact that, if a line is drawn along Grant Road, the highest mortality occurred to the north of this line, commencing on the east; the sections of the highest mortality being immediately to the north of the line, *i.e.*, 2nd Nagpada and Kamathipura. While the third section of the line is Tardeo, in which the mortality was 79·71. Further north still, to the immediate north of Nagpada, is Byculla, with a mortality of 80·71; and further on Parel, with the fourth highest mortality. And the sections to the south of the line are localities of very high mortality—Khara Talao with a mortality of 64 and Kumbharwada with a mortality of 58. To the south of these sections and the south of this line the mortality declines; for immediately further south is the Market, with a mortality as low as 27; and further south, the Esplanade, a section in which the mortality fell to 16. But further south still, the mortality in the Fort North rises to 34; and further south still, in Middle Colaba, to 48.

It is a most interesting fact that in some of the most crowded portions of the central portions of the city the mortality in this year of plague and of panic was comparatively low. In the sparsely populated districts in the suburbs, the mortality has been higher than in densely populated localities, such as the Market and the Fort North. This may partly be explained by the migration of the people in 1896–97 from the city to the suburbs in the north of the Island. A very great movement of population did take place to the northern suburbs, and the disease did not follow that migration as I pointed out in the Report for 1896.

It is also interesting to observe that the mortality in Chaupati for the whole year is lower than on the favourite hills of Walkeshwar and Mahalakshmi; and Chaupati extends to the bottom of these hills.

The old-fashioned building of the suburbs, though it may be in a field, has a number of dark rooms with less ventilation than the rooms in the immense chawls in the city. Even in the military lines on the Esplanade we saw done what the people are doing in the suburbs—verandahs carried out far and so low that the inner rooms were left without wholesome light and air. And so it is, although there may be open space around the old-fashioned buildings in the suburbs, there are inner rooms in darkness, into which the light from outside cannot enter, nor the air freely pass.

Small Pox.—During this year the mortality from small-pox has been very small. 57 deaths were registered, being 644 less than in 1896 and 392 less than the average. Small as the mortality from small-pox was, the incidence was distributed by sections, as in 1896, when the disease was epidemic. It fell heaviest on the most insanitary and most undrained districts. The greatest number of deaths were registered in the Nagpadas. The mortality from small-pox fell heaviest on females, as in previous years, and in the earliest periods of life.

Measles.—From measles there were 359 deaths, being 118 more than in 1896, but 155 less than the average. The distribution of the mortality by classes is the same as in 1896, the highest mortality having occurred amongst Hindu low-caste, and the next highest amongst Mussulman. The mortality by sections follows nearly the same incidence as in 1896, being highest in 2nd Nagpada, Byculla, Tardeo, Kumbharwada, Kharatalao and Kamathipura—all sections of high mortality in 1896.

Fevers.—As the mortality from plague decreased, the mortality from fevers generally declined. All through this monsoon, in July, August, and September, there was a serious increase in the mortality from fevers, concurrently with the prevalence of cholera. In July the mortality from fevers rose to 457, in August to 593, and in September to 567. Through October and November the fever mortality declined to 422 and 324, to again increase in December. The mortality from fevers generally decreased greatly in February. In January 1,836 deaths were registered from fevers, while in February the number fell to 1,006. It was conjectured that the high mortality in January from fevers was due to deaths from plague, being included in the general fever mortality. If this occurred in January, it must also have occurred in February. Against this belief is the fact that,

after the operations of the Plague Committee commenced, and when concealment of plague cases became more general, the mortality from fevers did not rise.

The decrease in February in the mortality from fevers occurred amongst all classes except Parsees ; and in this class mortality slightly rose, to be followed by a great decline in March. Again in July the number of deaths from fevers commenced to increase with the rise in the general mortality. The mortality from fevers registered amongst Parsees was exceptionally low, being 2·7. It seems to me that this clearly shows that in the Parsee community deaths from plague could not have been largely referred to fevers generally. Throughout the monsoon the mortality from fevers amongst Europeans was higher than in the epidemic period of plague.

Compared with 1896 the mortality from fevers was lower in all classes. It is a curious fact that the mortality from fevers amongst Brahmins was below the average. Among the Hindu population generally the mortality in 1897 was less than in 1896, and very nearly normal.

The number of deaths registered from fevers was 6,951, being 1,825 less than in the last year, and 95 less than the average. Of the fever deaths, 5,904 were referred to remittent fever, being 1,389 less than in the last year, but 155 more than the average ; 789 were ascribed to simple continued fever, being 378 less than in the last year and 178 less than the average ; 225 were due to ague, being 55 less than in the last year and 78 less than the average ; 33 were referred to enteric fever, being 3 less than in the last year, but 6 more than the average.

The highest mortality from fevers occurred in Parel, Sewri, Kamathipura, 2nd Nagpada, Byculla, and Tardeo. The high mortality from fevers in these districts may be ascribed to imperfect recognition of plague. Yet in suburbs, such as Parel, Sewri, and Mahim, the discovery of concealed cases was comparatively easy. I ascribe it rather to difficulty of recognition of the disease during life, and neglect of medical assistance. It will be observed that in some of the most crowded localities, as the market, where concealment of cases is very easy, the mortality from fevers was lower than in the suburbs.

Cholera.—During the rainy season a serious recrudescence of cholera occurred. 1,265 deaths were registered, being 775 more than in 1896 and 1,001 above the average. From April to August the mortality progressively increased. Arranged by months, the incidence of the mortality takes the same line as in 1896. There is a marked increase in July, rising to a maximum in the beginning of August.

The influence of the proximity of damp ground on the incident of cholera is well shown by statistics. Of 1,480 cases, as many as 879, or more than 59·39 per cent. occurred on the ground floor. The explanation, I believe, is that which I offered last year : the development of cholera germs in the muddy or damp ground around or in dwellings, and the greater exposure of people sleeping on the ground floor to them.

In all 1,480 cases of cholera were reported, 1,265 of which proved fatal.

I have already drawn attention to the fact that the mortality from cholera has been highest in the suburbs to the north and south. Byculla and the sections close to it suffered most in the north ; while Middle and Lower Colaba were most affected in the south.

As in 1896, the highest mortality occurred amongst Hindu low-caste and Native Christians. It is remarkable that the classes who suffered most are probably the classes most careless about their food and water.

The mortality by age periods follows the same incidence as in former years, being highest between 30 and 40 years of age.

Phthisis.—From phthisis 5,927 deaths were registered, being 1,118 more than in 1896 and 2,153 over the average. The mortality from phthisis follows nearly the same incidence as in former years. It has in each year pointed to the great loss of life caused through seclusion in crowded and ill-ventilated dwellings. The female mortality has been more than double the male, and this loss of life falls on Musalman and high class Hindus. Even amongst poor Hindus, notwithstanding the laborious lives the women live and the privations they have to endure, the mortality is relatively low—under 6 per 1,000. The sections of highest mortality from phthisis are the most overcrowded and ill-ventilated sections of the city. The sections of ill-repute are 2nd Nagpada, Umarkhadi, Chakla, Bhuleshwar, Khara Talao and Kamathipura ; and they have always been sections of the highest mortality, and not one of them has any open space for ventilation and recreation. The mortality from phthisis also indicates that the death registration in 1896 was not so defective as in 1897, exactly the same sections are sections of high mortality in 1897 as in 1896. It was contended in 1896 that, under the mortality from phthisis

were registered a number of deaths from plague. But judging from the statistics of 1897, it does not seem to have occurred to any large extent, nor does the error from this cause appear to have been so serious as was apprehended.

The mortality from phthisis in 1897 must be viewed with considerable suspicion, as there is little doubt that the enhancement of the phthisical mortality was due to either cases of plague being mistaken for phthisis, or to the concealment of plague, under this cause. The total mortality—5,927—is 1,118 higher than in 1896. The distribution of the mortality by sex shows that it is 1·39 higher amongst males and 1·31 higher amongst females than in that year.

From diseases of the respiratory system 7,857 deaths, being 2,523 more than in 1896 and 2,970 more than the average, were registered. Of these deaths 4,830 were referred to bronchitis, being 1,809 more than in the last year and 1,893 more than the average, and 1,332 were referred to pneumonia, being 258 less than in the last year but 41 more than the average. The mortality from diseases of the respiratory system was highest in 2nd Nagpada, Kharatalao, Kamathipura, Umarkhadi, Chukla, and Dongri. These are also the sections of highest mortality from phthisis. All these sections have great density of buildings and an overcrowded population.

APPENDIX.

No. 1.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner with the Government of India for 1897.

Unlike those of its immediate predecessor, the meteorological features of the year, for India as a whole, were not to any marked degree abnormal. Although the South-West monsoon was late in arriving, it was favourably distributed and was followed by good harvests. "The mean humidity for "the whole year for the whole country was slightly below the normal." Excepting in Assam and parts of Burma the temperature was in excess in May, and very generally excessive over India in June. Otherwise the climatic conditions of the year did not much differ from those which ordinarily prevail.

2. The European Army of India, of an average strength of 68,395 men, was less healthy than during the previous year. This diminished healthiness was due, in part, to increased prevalence of diseases of malarial origin, and in part to exposure and injuries on field service. The diseases, however, to which sickness and mortality were mainly due, were the same in both years. The chief causes of admissions into hospital were venereal diseases and ague, the former accounting for a ratio of 487·7, and the latter of a ratio of 394·7, or, together, 882·4 of the total ratio of 1,557 admissions. Although the chief causes of admissions, these two diseases were not equally prevalent during both years. The admissions from venereal diseases decreased from a ratio of 511·6 per thousand of strength in 1896, to a ratio of 487·7 in the year under report; whilst those from ague rose from a ratio of 239·0 in the former to a ratio of 394·7 in the latter year. With regard to the reduction in the ratio of admissions from venereal diseases, the Sanitary Commissioner with the Government of India says, "it appears to "have been connected with the employment of a large number of men on field service in the second "half of the year, as the number of venereal admissions was much lower from July to December "than from January to June." The great increase in the prevalence of ague is attributed to "increase of malaria consequent on the prolonged drought followed by an abundant monsoon." Besides fevers, some of the other diseases which contributed to the increased ratio of admissions were cholera and bowel complaints. Of the total sickness, venereal diseases caused 31 per cent., and ague 25 per cent. As usual, enteric fever was the most fatal of all the diseases. Of the total ratio of 22·93 deaths per thousand of strength for the year, this disease alone accounted for 9·01, or 39 per cent. The other diseases which contributed most to the mortality were dysentery, hepatic abscess, and cholera; but the combined mortality due to these three was equal to a ratio of only 4·99, or little more than half of that due to enteric fever by itself. The rise in the death-rate from all causes over that of the previous year was great. Whilst the ratio recorded for 1896 was only 14·84, and for the decennium 1886–95 only 15·16, that for the year under report was 22·93. The loss due to invaliding at the same time rose from a ratio per 1,000 of strength of 28 in the preceding year, and of 24 in the decennium 1886–95 to 33 in 1897; whilst the total loss, from death and invaliding combined, rose to a ratio of 56 per thousand of strength as compared with 43 in the previous year, and with 39 in the preceding decennium. Amongst the causes which necessitated invaliding the first place was taken by secondary syphilis. The total number invalided during the year was 2,258, and to secondary syphilis alone 611 of this number were due. The diseases which most closely followed secondary syphilis as causes of invaliding were debility, malarial fevers, and tubercle of the lungs; but the total number invalided on account of these three causes combined, amounted to only 456 as compared with 611 from secondary syphilis by itself.

3. As in the previous year, of the four Commands, the Bengal Command was the most unhealthy and the Madras Command the most healthy. The total death-rate of Madras only reached to 56 per cent. of the death-rate in Bengal. In point of mortality the Punjab Command followed Bengal very closely: in the former the death-rate per thousand of strength was 21·52 and in the latter 23·32. So, on the other hand, did the mortality in the Bombay Command closely approximate to that of Madras: in the former the death-rate was 13·10 and in the latter 14·33. But although the Madras Command shows the lowest death-rate, its constantly-sick rate was higher than that of either the Punjab or Bombay. Its admission-rate, however, was the lowest of all the Commands, a result mainly due to its comparative immunity from intermittent fever. The ratio of admissions into hospital from this disease was only 121·5 per thousand of strength in Madras as compared with 356·1 in the Bengal, 406·4 in the Bombay, and 442·5 in the Punjab Command. Intermittent fever, although largely influencing the admission-rate, had little effect on the death-rate: in neither of the Commands did this reach ·5 per thousand of strength, and it was lower in Bombay than in Madras. The diseases mainly concerned in creating the striking difference between the death-rates in the Madras and Bengal Commands were cholera and enteric fever. Whilst the former of these diseases was credited with a death-rate of 3·28 in Bengal, the rate was only 0·32 in Madras; and whilst enteric fever had attributed to it a death-rate of 10·39 in Bengal, the rate was only 4·93 in Madras. In the Punjab the mortality from enteric fever was still greater than in Bengal, and was the chief cause of the high

death-rate in that Command, accounting as it did for 11·05 of the total death-rate from all causes of 21·52. But for the somewhat greater fatality from enteric fever in the Bombay than in the Madras Command, the death-rates in these two Commands would have been almost the same. Of loss from invaliding, on the other hand, Madras gives by far the highest ratio per thousand of strength; whilst the Punjab gives the lowest. In the latter this ratio was only 21·9 as compared with 31·8 in Bombay, 40·9 in Bengal, and 47·5 in Madras. As already stated, to no disease was invaliding so largely due as to secondary syphilis; and the Madras Command had, "as usual," the highest ratio of cases of secondary syphilis.

4. Comparing the ratios of sickness and mortality of the troops according to Geographical Groups, it is seen that the constantly-sick rate was lowest in the Western Coast, and highest in the Rajputana, Central India, and Gujrat Group. In the former group the rate was 76·9 per thousand of strength as compared with 127·7 in the latter. In respect of mortality from enteric fever, more especially, these two Geographical Groups differ widely. The ratio of mortality from enteric fever per thousand of strength in the Western Coast Group was only 3·40; whilst in the Rajputana, Central India, and Gujrat Group it was 20·16. In the previous year, however, the positions of these two groups with respect of enteric fever mortality were reversed; the ratio in the former having been 10·28 as compared with 8·39 in the latter. The strength of the garrison of the Western Coast Group was only 1,471, and ratios calculated on numbers so small are liable to fluctuate from year to year between somewhat wide limits. "The percentage of enteric fever to total admissions in 1897 was greatest in the hills."

5. Of the larger stations with garrisons exceeding in strength 1,000 men, Agra, Peshawar, Meerut, Mhow, and Umballa, show the highest death-ratios. "All these stations had increased mortality from enteric fever." Yet two of them, Agra and Meerut, are supplied with filtered pipe-water from the municipal waterworks. Regarding Meerut it is stated in Table V. that "the water-supply is good and abundant, and there is no source from which it is liable to be contaminated." In the same table it is stated, with regard to the prevalence of enteric fever at Agra, that the disease "was almost certainly due to contamination of the municipal water-supply." Again, in the case of Peshawar we find the remark "there is no defect in the water-supply, which comes into the station direct from the Bara River in pipes through filtering beds." Of Umballa, it is said:—"The disease in the first "instance was due to exposure on military service in an unhealthy climate; in the second to "drinking of contaminated water by men recently arrived in the country. The prevalence of the "disease was due to the drinking of contaminated water from a disused well." Thus, in two of these four stations, the water-supply is described as having been free from objection, and yet one shows a death-rate from enteric fever of 18·58 and the other of 26·93: in the other two the water was condemned as being contaminated, and the enteric fever death-rate was in the one 15·32 and in the other 45·04.

6. *Principal Diseases.*—There was a marked decrease in the prevalence of *influenza:* the ratio of admissions into hospital fell from 11·5 per thousand of strength to only 4·0. Not only was the disease less prevalent, but it was apparently also of a milder type. Whilst the average number of men constantly sick with influenza was 10, against 61 in 1896, the average duration of a case was only 13 against 28 days.

7. *Cholera* was more fatal than during the preceding year and accounted for 80 deaths, as compared with 63 in 1896. In the single station of Sitapur no fewer than 41 of the 80 deaths took place. There was in this station a garrison of only 435 men when the disease broke out, and of this small number 65 were attacked by cholera and 41 died. As exemplifying the influence of anti-cholera inoculation in conferring immunity in the case of a small number of men who had submitted themselves to be operated upon, we read at page 149 of the Report:—"Among the 27 inoculated men "four were attacked and two died. So that, among the uninoculated the percentage attacked was "14·9 and the case mortality about 63 per cent., while among the inoculated the percentage attacked "was 14·8 and the case mortality 50 per cent." From the results obtained in the case of numbers so small, it would be unsafe to generalise; but so far as they go they cannot be said to lend much support to the belief of those who maintain that in anti-cholera inoculation, as at present practised at all events, they have discovered an effectual means of cholera prevention. In our *memoranda* on the Provincial Sanitary Reports we have dealt with the question of the influence which the disinfection of water-supplies seemed to exercise in the prevention of cholera. The results so far, although by no means conclusive, seem to support the belief that disinfection is, on the whole, beneficial. As the Sanitary Commissioner with the Government of India concisely puts it:—"The experience of the "year teaches little that is new in the prevention and treatment of epidemic outbreaks of cholera in "India. The old lessons are repeated; cholera cannot be prevented by any single precaution, and no "possible precaution should be omitted; when the disease appears in epidemic form, prompt "movement, intelligently carried out, is the most effective check."

8. Of *small-pox* there were 24 cases with 4 deaths, as compared with 122 cases and 10 deaths during the previous year. The admission-rates and the death-rates were both below the decennial ratios of 1886–95.

9. *Intermittent, remittent,* and *continued fevers* were all greatly more prevalent than in 1896. In the present, as in the previous Report, the Sanitary Commissioner shows that some of the medical officers differ as to where they draw the line between simple continued fever and enteric fever, as well as between the former and ague. Likewise, with the decrease of ague and influenza recorded in Burma Coast, a great rise is noticed in the number of cases of simple continued fever. In explanation of this the Medical Officer at Rangoon notes that what is called by one medical officer "influenza" may by another be designated "simple continued fever."

10. Regarding the prevalence of *enteric fever* in 1896, we noted that it continued its destructive course without substantial abatement. The ratio of deaths caused by it in that year was 6·31 per thousand of strength of the European Army of India: in the year under report this ratio has risen to

9·01. During the previous year the enteric fever deaths numbered 445 : during 1897 they numbered 556. There has thus been not only no diminution but a large increase in the mortality caused by the disease. As might have been expected, the question of the growing prevalence and fatality of enteric fever is very fully dealt with in the Report. The opinion so long maintained by many that enteric fever is solely a water-borne disease, is in process of giving way before an accumulation of evidence tending to show that the enteric bacillus is much more widely diffused than has generally been supposed. Indeed, so various and numerous do the sources of infection appear to be, that if prevention is to be attempted with any reasonable prospect of success, attention cannot be exclusively concentrated upon securing purity of the soldier's water-supply, but must be bestowed on every detail of his environment. Hitherto, when a case of enteric fever has appeared, it has too often been the custom to jump at once to the conclusion that the water-supply alone was at fault, and to proceed to support this assumption by an investigation exclusively devoted to the water-supply. If the enteric fever bacillus has not been discovered in the water, it has been considered sufficient to repeat the customary condemnation of the supply by declaring it to be, at all events, "liable to contamination," a description which might very often be applied to water-supplies. The question of the causation and spread of enteric fever in the European Army of India, is dealt with in the Report in the light of our most recent knowledge and in a spirit of open-mindedness and impartiality not too common.

11. The admission-rate from *venereal disease* showed some decrease, but was still very high. From a ratio of 522·3 per 1,000 of strength in 1895, the rate decreased in 1896 to 511·6, and now in 1897 to 485·7. The table given at page 59 of the Report shows the admission rate for venereal disease year by year since 1872, the first year for which the records for India as a whole are available. From this table it is seen that the ratio of admissions from primary syphilis was 61·2 in 1872, and that it had only increased to 90·2 up to 1884. From that year, however, the increase was rapid, and the enormous ratio of 201·7 was reached in 1895. It will be seen from the table that secondary syphilis was almost stationary between 1872 and 1884 : in the former year it gave a ratio of admissions per thousand of strength of 22·4, and in the latter of 24·4. From 1884, however, its increase has been great, until the year under report, when a ratio of 101·9, the highest recorded, has been reached. This growing prevalence of secondary syphilis is a most unfavourable feature of the history of venereal disease in the European Army of India. There were 23 deaths and 662 invalidings *directly* due to venereal disease, against 14 of the former and 479 of the latter in the preceding year. From this it is evident that the slight decrease in the admission-rate, cannot be taken as an indication of any corresponding abatement in the destructive effects of the disease during the year under report. The number of men constantly sick in hospital from venereal disease in 1897 was 2,991·59, equivalent to about three regiments. Such figures may be left to tell their own tale. Those who are not convinced by them of the alarming ravages of venereal disease amongst our young soldiers, and of the urgent need for the adoption of all practical measures for holding it in check, would not be convinced by any description of the physical ruin it inflicts on its victims and on their posterity. A visit to the wards of the Netley Hospital might help to dispel the doubts of those who still continue to regard with scepticism the official figures showing the havoc annually wrought by venereal disease amongst the soldiers of the European Army of India.

12. Sickness and mortality were greater in the *Native Army* than during the preceding year, but were much less than in the European army. Whilst in the latter the ratio of admissions into hospital was 1,557 per thousand of strength, in the Native Army it was only 839, or not greatly over half. The constantly-sick rate was, at the same time, more than three times greater in the European Army, and the death-rate 22·93 as compared with 14·90. Although the ratios of sickness and mortality in the Native Army were considerably higher in the year under report than in 1896, they were below those of the ten-year period 1886–95. The chief causes of admission were ague and dysentery, ague alone causing 41 per cent. of the total admissions. The Sanitary Commissioner with the Government of India writes :—"Owing to the arrival of an abundant monsoon after a "prolonged period of drought, there was an increase of malaria, and therefore of fever and mortality "in 1897 as compared with 1896. The sickness and mortality were also raised by the employment "of a large body of men on active service." The contrast between the comparative immunity of the Native Army from diseases which are the scourge of the European Army is as striking as usual. Whilst in the Native Army the death-rate from enteric fever was only 0·12 per thousand of strength, it was 9·01 in the European Army. Likewise, whilst amongst the native troops the rate of admissions into hospital from venereal diseases was only 40·8 per thousand of strength, it was in the European Army 485·7 On the other hand, pneumonia was accountable for a death-rate of 2·73 in the Native Army and of only 0·60 in the European Army, and remittent fever of 1·04 in the former as compared with ·60 in the latter. Cholera, dysentery and hepatic abscess were greatly more fatal in the European than in the Native Army, the ratios for these three diseases having been, consecutively, in the former 1·17, 2·53, and 1·29, as compared with ·52, ·67, and ·06 in the latter.

13. Whilst the European Army had only five admissions and no deaths during the year from *plague*, the Native Army had 131 admissions and 82 deaths. The disease was confined to the Bombay and Madras troops. As with cholera, so with plague, evacuation of the infected quarters occupied by the troops has been found to be the most effectual measure yet discovered for cutting short an outbreak of the disease. At the conclusion of a full account of the plague, covering upwards of 40 pages, the Sanitary Commissioner says :—"One of the great lessons to be learned "from Indian experience is, that simple isolation of the sick and of those who have been in contact "with them is of no ultimate use. Nothing short of total evacuation is certainly effectual, total "evacuation involving life in fresh open air at a considerable distance from the infected locality." Increased experience and knowledge of the modes by which plague may be propagated, have tended to bring about a modification of the measures on which reliance was placed in the earlier days of the epidemic to check the progress of the disease. The part which rats and other animals play in the propagation of plague has not yet been fully worked out ; but if this part is at all of the importance which Hankin and other scientific observers seem to attach to it, the position taken up by those who would rely on land quarantine to prevent the spread of plague becomes much weakened and

scarcely tenable. Much knowledge has been accumulated since the first appearance of the disease in Bombay in September 1896; but, as Hankin puts it, "caution and reserve are still needed, and, "still more, further research," before some of the most important questions connected with the mode of development and propagation of plague can be regarded as finally settled.

14. *Jails.*—During a year in which famine and scarcity prevailed in many of the provinces, it was only to be expected that the health of the prisoners, like that of the general population from which they are drawn, should suffer. There was a considerable increase in the average strength of the jail population, which rose from 110,186 in the preceding year to 118,107 in the year under report, an increase due in part, if not altogether, to the pressure of want driving the starving to the commission of breaches of the law in order to try and preserve their own or their dependents' lives. The admissions into hospital increased from a ratio per thousand of strength in the previous year of 983, to a ratio of 1,045; and, although the constantly-sick rate of 41 was the same in both years, the death-rate rose from 27·68 in 1896 to 38·75 in 1897. The death-rate from cholera was more than twice as high as in the previous year, and the death-rate from dysentery and diarrhœa almost twice as high. The death-rate from dysentery increased from 5·91 to 11·07, and of diarrhœa from 1·98 to 3·17. The excessive prevalence of these two so-called "famine diseases" may be taken as some measure of the sufferings from insufficient and unsuitable food of the population from which the prisoners are drawn. The overcrowding to which the increase in the jail population gave rise in many provinces, might have been expected to increase the mortality from respiratory diseases and phthisis pulmonalis; but such was not the case: there was even a slight decrease in the mortality from both of these causes. The pressure on the available accommodation was great, and a reference to the "Abstract of the Sanitary Sheets of the most Unhealthy Jails" shows that out of 82 jails so described, overcrowding existed at some period of the year in no fewer than 64. "Plague "accounted for 37 cases with 20 deaths, all in jails of the Bombay Administration."

15. The remaining sections of the Report, dealing as they do with vital statistics, chief diseases of the general population, vaccination, and sanitary works, do not call for remark here: these subjects have been noticed in the several *memoranda* on the Provincial Sanitary Reports. And here we venture to make a remark on the increasing bulk of the Annual Report of the Sanitary Commissioner with the Government of India. The Report for 1894 had attained an enormous size; but relief was found by the substitution of the present concise tabular statements for those previously in use. Chiefly as a result of the recasting of those statistical tables, the report was reduced from a total of 528 pages to 374 in 1895. This welcome reduction in bulk proved, unfortunately, to be only temporary. In the following year the Report again increased to 422 pages; and now in 1897 to 492, or to nearly the number contained in the ponderous volume prior to the recasting of the tabular statement. No doubt, a considerable portion of this increase has been due to the necessity for dealing adequately with the history of an additional and formidable disease, the Plague. But although the rapid increase in the size of the report may be justified, we trust that it may be found possible in succeeding years, if not again to reduce it, at all events to check its further growth. No one who has read it will deny that the present Report is one of marked excellence; but the number of its readers will, we fear, be limited by its size.

16. *Summary.*—There was a great falling off in the healthiness of the European Army of India during the year under report, as compared with the preceding year. The ratios of admissions into hospital, of deaths, and of invalidings all showed an increase. Greater prevalence of malaria, due to climatic conditions, and exposure on service in the field, were concerned in bringing about this increase of sickness and mortality. The rise in the death-rate was largely owing to greater fatality from enteric fever, cholera, and dysentery. The first of these three diseases caused no fewer than 556 deaths of a total from all causes of 1,214. Cholera caused 80 and dysentery 82 deaths. Of the four Commands, Madras had the lowest death-rate: this only reached 56 per cent. of the death-rate in the Bengal Command, in which it was the highest. The rate of admissions from venereal diseases decreased from 511·6 per thousand of strength to 485·7, a result which appears to have been connected with the employment of a large number of men on field service in the second half of the year. On the other hand, there was a deplorable increase in the amount of secondary syphilis. To this disease alone no fewer than 662 invalidings were directly due. Little of importance has been added to the knowledge already accumulated regarding cholera, against which 80 deaths are recorded. The opinion so long maintained by many that enteric fever is exclusively a water-borne disease, seems to be giving way before the results of further observation and research. Evidence is being collected which shows that the cause of the disease is more widely diffused than has generally been suspected. Meanwhile, its ravages show no tendency to decrease, in spite of the unremitting attention devoted to the soldier and his environment. As in the case of the European Army, so in that of the Native Army, the year was less healthy than its predecessor. The ratio of admissions into hospital in the Native Army did not, however, very greatly exceed half the ratio in the European Army, and the death-rate was 14·90 as compared with 22·93 in the latter. There was, as in former years, the same comparative immunity of the native troops from enteric fever and venereal disease, and the same greater fatality from pneumonia and remittent fever. The Native troops suffered less from cholera, dysentery, and hepatic abscess than the European troops. Plague mortality was confined to the troops of the Madras and Bombay Commands. According to the returns, five men of the European Army were attacked but none died. The jail population in 1897, owing to the prevalence of scarcity and famine, was greater than in the preceding year, and this increase led to some overcrowding in many of the jails. The death-rate amongst the prisoners was higher than in 1896, cholera and bowel complaints having been greatly more fatal. Since its reduction in size in 1895, the Annual Report has again been rapidly growing in bulk, and it is suggested that, if it cannot again be reduced in size, an effort should be made to check its further increase.

14th August, 1899.

No. 2.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bengal for 1897.

The year was in some important respects in marked contrast with its predecessor. Besides being deficient in quantity and irregularly distributed, the rains of 1896 ceased prematurely, leaving the winter rice crop over large areas to wither. During the year under report the rainfall was generally in excess of the mean, seasonable, and followed by abundant harvests. The scarcity and famine of the concluding months of the previous year continued throughout the first nine months of 1897. But for the privations to which the population of the tracts affected by scarcity or famine were subjected, and the general prevalence of high prices, the year would undoubtedly have been one of low mortality. Notwithstanding the prevalence of scarcity and famine, the death-rate for the Province was considerably less than in the previous year. The Sanitary Commissioner is no doubt correct in attributing this result chiefly to the abnormal dryness of the preceding year. "It is " remarkable that the mean temperature of nearly every district during every month of the year was " higher than the normal mean." Dr. Dyson thinks that the dryness of the previous year might account for the high temperatures of the first months of 1897, but is unable to say why these should have continued throughout the rains and cold season. The year was thus characterised by an abundant and seasonable rainfall, by abnormally high temperature, by famine affecting fifteen districts, and by high prices over the Province generally.

2. *Vital Statistics.*—The *birth-rate* of the year was, of course, largely influenced by the conditions affecting the public health during the preceding year. In the fifteen districts which were affected by famine during that year, the birth-rate underwent a decrease. For the Province as a whole, the birth-rate was 36·94 per thousand of population as compared with 38·03 in 1896. Patna, the division of the Province in which the famine was most severe, shows the lowest birth-rate. In this division, with its population of nearly sixteen millions, the birth-rate was only 33·93. In Chota Nagpur, the other division severely affected by famine, the birth-rate fell from 40·25 in 1896 to 34·82 in the year under report. The Sanitary Commissioner shows that scarcity and famine acted in reducing the birth-rate in two ways: by lowering the vitality of the people and so lessening their fecundity, and by compelling a large number of the males to leave their homes in quest of employment elsewhere. Although improvement in the registration of vital statistics has within the last few years made, and is still making, remarkable progress in Bengal, a comparison of the recorded with the estimated birth-rate of about 50 per thousand of population for the Province shows that a considerable proportion of the births probably still remains unregistered. Unless to difference in the efficiency with which registration is carried out, it is difficult to suggest other sufficient causes to which the great differences between the death-rates of many of the districts can be due. Excluding Calcutta, in which the conditions are exceptional, the birth-rate ranges between 47·40 in the Malda district and 28·97 in the Pubna district. In towns the variations are still greater, ranging between 52·62 and 2·11. No doubt some of the other causes mentioned by Dr. Dyson may contribute to the production of these variations; but in the score of towns returning a birth-rate of less than 20 *per mille* of their population, defective registration is probably the main if not the only cause.

3. The *death-rate*, chiefly owing to less mortality from cholera and fever, fell from a ratio of 34·17 per thousand of population in the preceding year to 32·94 in the year under report. This ratio is still 5·27 above that of the previous decade; but this result is no doubt rightly attributed by Dr. Dyson " to imperfect registration during the earlier years of that decade." As with the birth so with the death-rate, the ratio per thousand of population varied within wide limits in the rural areas of districts, and still more in towns. Whilst Chittagong records a death-rate of 49·92 in its rural areas the 24-Parganas district records only 23·62; and whilst amongst towns Lohardaga records 89·59 Maniktala records only 14·20. The enormous ratio of 152·94 in Chakaria, a rural circle in the Chittagong district, is " due to the large number of people, 5,377, who perished in the cyclone of 24th October." Of the four great natural divisions of the Province, Bihar shows a diminished mortality from all the chief diseases. Its cholera death-rate was only 1·48 per thousand of population as compared with 3·41 in the previous year, and was by far the lowest recorded in any of the divisions. From this it would appear that there is no necessary connection between famine and cholera prevalence. Its death-rates from fever, dysentery, and diarrhœa were also less than in 1896. In Chota Nagpur, the other division which suffered most severely from famine, entirely opposite results were recorded. The mortality from each of the chief diseases shows in this division an increase. Cholera was nearly six time more fatal than in the previous year, small-pox nearly three times, dysentery and diarrhœa more than twice as fatal; whilst the fever death-rate rose from 22·34 to 24·77 and was the highest recorded in any of the divisions. Regarding the abnormal mortality from cholera in Chota Nagpur, the Sanitary Commissioner considers that it " was due to four out of the five districts comprising the " division having suffered more or less severely from famine, which weakened the general vitality of " the people by a long course of insufficient and unsuitable food and thus predisposed them to cholera " and bowel complaints." But the people of Bihar also suffered from severe famine, and yet the mortality amongst them from both cholera and bowel complaints was lower than amongst the people of any of the other divisions, lower than in the preceding year, and lower than the average of the preceding ten years. It is certain, however, that the inhabitants of the jungle-covered tracts of Chota Nagpur suffered more than did those of Bihar from the use of unsuitable articles of diet, numbers of them having been driven to subsist mainly on jungle roots and fruits when their crops failed and the high price of grain placed it beyond their means of purchase. Whatever influence

such an unsuitable dietary may have had in rendering them liable to cholera, it is certain that the prevalence and fatality of bowel complaints were largely increased by it.

4. *Chief Diseases.*—Cholera, although considerably less fatal than in the previous year, was yet present in every district of the Province and accounted for 196,247 deaths. The two districts in which the disease proved most fatal were Puri and Chittagong. In the former, which always suffers badly, periodical outbreaks of the disease are shown to have been coincident with the crowds of pilgrims attending the different religious festivals; and in Chittagong, in which there were two severe outbreaks during the year, the Civil Surgeon attributes the first to the dirty condition of the tanks consequent on the prolonged drought, and the other, partly to the effects of the destructive cyclone which drifted leaves and other *débris* into the tanks, thereby polluting the water, and partly to the use of excessive quantities of bad-smelling fish at the time when food became temporarily dear within the area visited by the cyclone. In some districts, the outbreaks are attributed by the Civil Surgeons to deficient and polluted water-supply following the scanty rainfall of the previous year, and to the deterioration of tanks, wells, and streams caused by the upheaval of their beds by the earthquake of the 12th of June. The disinfection of wells with lime or permanganate of potash was tried in fifteen districts; but from five of these no definite results were reported. In the other ~~ten~~ districts, disinfection is said to have been attended with beneficial results. A tabular statement is given showing the effect on the mortality from cholera which followed the disinfection of wells in the town of Ranchi. The table gives the number of deaths from the disease during the fortnight preceding the disinfection, and the number during the fortnight following the disinfection of the wells. The comparison of the cholera mortality in the two fortnights is very striking; in fact, so striking as to suggest that disinfection by these chemicals might not have been the sole cause to which the decrease was due. Adding up columns 6 and 7, it will be seen that, whilst there were 42 cases and 18 deaths in the fortnight preceding disinfection there were only four cases and three deaths after disinfection. No one will hesitate to credit the purification of the water-supply with a beneficial effect in arresting the progress of cholera; but it is open to question if, supposing the disease had been allowed to pursue its course, and disinfection had not been tried, the mortality during the second fortnight would have been as high as that of the first fortnight with which it is compared. The violence of the outbreak may have to some extent spent itself in the former fortnight. Besides, as seems to be the opinion of the Sanitary Commissioner of the Central Provinces, it is probable that the ordinary measures invariably taken for cleansing wells, and for protecting them against pollution so soon as an outbreak of cholera declares itself, may have been important factors in checking the disease. So far as they have gone, these experiments have undoubtedly given promising results; but their numbers will have to be greatly multiplied, and they will have to be carried out systematically and with scientific precautions against error before the real value of chemical disinfectants, and their mode of action in destroying the cause of cholera present in water, can be definitely determined. The record of results of anti-cholera inoculations is still incomplete. By far the greater number of inoculations were performed on emigrant coolies bound for the tea gardens in Assam. Out of a total of 10,950 inoculated, no fewer that 7,620 were of this class; and seeing that the loss of life from cholera annually occurring amongst these coolies whilst in transit from the recruiting depôts in Bengal to their destination in Assam has hitherto been lamentable, the cessation of this loss, should it now result, would go some way to establish the claim of inoculation to confer immunity from the disease. "A complete and accurate record of the results "is expected within a short time" from the Assam Government, which is deeply interested in any measure offering reasonable promise of success in checking cholera mortality amongst the immigrant tea-garden coolies.

5. *Small-pox* was considerably more fatal than during the previous year, accounting for 19,655 deaths, as compared with 13,388 in 1896. Of the 46 districts of the Province, six contributed no fewer than 12,970 of the total number of small-pox deaths. In two of the six districts in which the disease prevailed in epidemic form, the Civil Surgeons attribute the outbreaks to the introduction of infection from other districts. Puri, it is stated, was infected from Ganjam, a neighbouring district of the Madras Presidency. In our Memorandum on the Madras Sanitary Report for 1895, the following quotation from that report occurs: "With the prospect of special increase of small-pox "following introduction from other Presidencies it remains to be seen during 1896 how far Madras "has been capable of resisting the invasion." If the Civil Surgeons of Puri and Shahabad, as well as the sanitary authorities in Madras, would make inquiry as to the degree of protection conferred by vaccination on the population within their respective spheres of influence, they would probably find reasons to satisfy them that it is unnecessary to travel beyond their own borders in search of the cause of small-pox outbreaks. In the Puri district, out of a total number of 27,924 children under one year of age available for vaccination, only 1,927 were successfully vaccinated, according to Statement No. I. of the Vaccination Report for 1897–98. In the Shahabad district the number of the same age available was 62,296; and of these only 4,505 were successfully vaccinated. Similar data are not so easily obtainable from the Madras reports regarding Ganjam; but it is gathered that there were 29,634 births in that district in 1897, and 8,853 deaths of children under one year of age, leaving available for vaccination 20,781; of this last number, 4,060 were successfully vaccinated. The number successfully vaccinated was, however, in a population of 1,836,519; whilst the number of births and the number of deaths of children under one year of age were in a population of 1,240,584. The Ganjam "district," consisting of three Circles according to the Vaccination Report, has a population of rather more than a third greater than the "district" of Ganjam according to Statement No. II. of the Sanitary Report. But even without reducing the number of successful vaccinations to meet this difference, it is seen that only one in every five of the children available for vaccination is protected against small-pox. With so great an amount of susceptible material in each of the districts mentioned, and with the infection of small-pox perhaps rarely, or never, absent from some parts of them, the causes of small-pox outbreaks are not far to seek. In the Province, as a whole, there was an increase of 25,881 vaccinations as compared with the number in 1896. As the the Sanitary Commissioner remarks:—"This is satisfactory, considering that the Province was just "recovering from the effects of a severe famine in some places, and prolonged scarcity in others."

The returns show a slight increase in the number of infants vaccinated ; but the proportion of these to the number available for vaccination is still very small, and amounts only to 208·18 out of every 1,000. With these figures as guides, there need be no delusions as to the causes to which small-pox epidemics are due. There was a considerable increase in the percentage of success in cases of re-vaccination. This percentage was 64·36 as compared with 52·59 in the preceding year, and, as Dr. Dyson remarks, "seems rather high." He adds, in explanation, that this high ratio of success "appears to be due to a considerable extent to the large number of vaccinations among adults who "have been vaccinated in their childhood, and in whose case the prophylactic power of the vaccine "virus had completely gone." The returns given on pages 15—19 of the Vaccination Report show that the all-important duty of inspecting the work of the vaccinators is carried out systematically and apparently with thoroughness.

6. *Fever* was credited with fewer deaths than in the preceding year. To the exceptional healthiness of the earlier months, owing no doubt to the early cessation of the rains in 1896, and the dryness and consequent decrease of malarial diseases which followed, was chiefly due this reduction of fever mortality. Coincident with decreased fever mortality, the sales of quinine at post offices fell off from 31,867 packets in the previous year to 27,915 in the year under report. This falling-off was probably not altogether due to decreased fever prevalence, but may have been, in part, due to the prevailing hard times and want of spare money for the purchase of medicines. The Lieutenant-Governor thinks that, "with the return of prosperity, a renewal of the demand for quinine may be "expected."

7. *Dysentery and Diarrhœa* were considerably more fatal than in the preceding year, and it is the opinion of many Civil Surgeons that the number of deaths recorded as due to these diseases was much below the actual number. The Civil Surgeon of Hazaribagh says : "No doubt a very large "proportion of the over 40,000 deaths returned as from fever more accurately should be returned "under this head, though fever whether symptomatic or really malarial probably was a sufficiently "prominent symptom to excite attention." The increase in the mortality from these diseases during the year was "almost solely due to the fact that, on account of the prevailing scarcity the poorer "classes of the people were obliged to live on herbs, roots, leaves of trees, and other unsuitable and "unwholesome food."

8. *Sanitary Works.*—"The total amount from all sources spent on sanitary works in urban and "rural areas during the year under report was Rs. 20,99,335 as against 17,61,776 in the previous year." This gives some measure of the progress being made. The amount seems small when compared with the vastness of the country, and its population of over 70 millions. One promising feature in the sanitary history of the year is the growing appreciation of sanitary improvement as exemplified by the sacrifices made in its behalf by private individuals. "The Lieutenant-Governor has observed "with pleasure that the value of works of sanitary improvement carried out by private individuals "shows a marked advance from Rs. 4,94,131 in 1896 to Rs. 11,67,469 in 1897." In Form XI., which appears for the first time in the Sanitary Report, an endeavour is made by the Sanitary Commissioner to give a concise description of the chief sanitary defects in the 147 municipalities of Bengal. The information given has evidently been collected with much care and labour. What strikes one most in its examination is the want of proportion between the death-rates of the different towns and the gravity of the sanitary defects recorded against them. Sanitation, for example, is very defective in the towns of Balasore, Arrah, Bankurah, and Kissenganj, yet their death-rates are, in the foregoing sequence, only 28·44, 28·14, 20·22, and 16·89 per 1,000 of their populations. On the other hand, sanitation does not seem to be worse in Gya, Serampore, Hazaribagh, and Lohardaga ; and yet there death-rates were respectively 54·27, 57·04, 78·51, and 89·59. It would seem from such comparisons that there must have been more potent influences affecting the death-rates than local insanitary conditions. In the case of the first group of towns named, one of these influences was most probably the neglect of registration of vital statistics. In the second group, famine drove numbers of half-starved wanderers into three at least of the four towns, and the high death-rates shown against them were, no doubt, largely due to the excessive mortality amongst these destitutes. The comparison is of use as showing that it would be unsafe to judge of the sanitary condition of towns from a consideration only of their death-rates. Regarding the precautions against plague, we read that the expenditure incurred on this account amounted to just over two lakhs of rupees. At inspection stations and observation camps for the examination of passengers coming by rail from infected areas "the total number of passengers examined was 1,181,792, of whom 17,994 were detained for "observation. Of these seven died, but in no case was plague the cause of death." This is a statement which it would be premature to deal with at present, whilst the whole question of the best means of arresting the progress of plague is engaging the attention of the Government.

9. Briefly, the season was, on the whole, healthy. In spite of widespread scarcity and famine the death-rate was lower than during the previous year. The early cessation of the rains in 1896 was followed by a prolonged period of drought, which doubtless reduced mortality from diseases of malarial origin during the first months of the following year. Registration has continued to improve rapidly since 1892. The recorded birth-rate shows a considerable decrease, and this decrease is mainly confined to the 15 districts in which famine was declared to exist during the preceding year. The lessened mortality of 1897 was chiefly due to decrease of fever and cholera. Dysentery and diarrhœa were more fatal than in the preceding year, especially in the Chota Nagpur division, in which scarcity and high prices drove many to subsist on jungle fruits and roots. Cholera, although it was less fatal than in 1896, appeared in every district of the Province and caused nearly two hundred thousand deaths. The disinfection of wells by chemicals seemed in some cases to produce a decided effect in checking the disease ; whilst in other cases it seems to have been followed by no definite beneficial results. Anti-cholera inoculation was largely practised on coolie emigrants to Assam, and an exact record of the effect is expected from the Assam Government. Fevers, as usual, caused by far the greater number of the deaths during the year. Drainage only will probably ever produce a large decrease in the prevalence of malarial fevers, and drainage on a scale sufficiently extensive to produce a sensible effect on fever prevalence in Bengal would have to be carried out at

vast expense. Small-pox was not specially fatal, yet accounted for nearly twenty thousand deaths. Vaccination makes progress, but still fails to reach more than about a fifth of the children under one year of age available for vaccination. A favourable feature in the sanitary progress of the year is the contribution of considerable sums of money by private persons for expenditure on sanitary improvement. It may be taken as some indication that the people of the country are coming to appreciate sanitation when they are willing to pay for its promotion.

9th June 1899.

No. 3.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the North-Western Provinces and Oudh for 1897.

The conditions of drought, high prices and famine, which characterized the latter part of the previous year, continued until the setting-in of the rains in June. The number of people in receipt of relief from the State rapidly increased from half a million in the beginning of January until it attained its maximum by the end of February, and was still over a million and a half in the first week of June. From the table given at the top of page 42 of the Report it appears that there were considerable showers of rain in the Provinces during January, but that until June the total fall did not amount in most parts of the country to two inches. The monsoon began in the third week of June and, on the whole, continued favourable until it finally ceased in the last week of September, With the setting-in of the rains the enormous numbers on the relief works rapidly melted away to till the fields, and by the end of September the famine was practically over. The temperatures of the year do not appear to have been very unusual. In the first two months the mean was above normal. and in the next two slightly below it. May was hotter and drier than usual, and before the monsoon burst the heat in June was intense. The temperature for the remainder of the year appears to have varied little from normal. High prices of food grains prevailed everywhere. To add to the anxieties of the year the Province was threatened with an epidemic of plague; but although the disease obtained a footing in a corner of a district, the vigorous measures taken to confine it to the locality in which it first appeared proved successful. In such a year, immediately succeeding a season of crop failure and high prices, the public health could not but suffer. There was a decrease in the number of births and an increase in the number of deaths. Taking into account the extent of country affected by severe and prolonged famine, the recorded death-rate cannot be regarded as high. Throughout the Report the census figures of 1891 are used as the basis on which ratios are calculated. The Sanitary Commissioner gives also the population numbers determined by adding the excess of births over deaths since the taking of last census. As thus calculated, it is seen that the "natural increase" of the population since 1891 has been somewhat over one million. This may be contrasted with the increase which took place between 1881 and 1887 of the preceding inter-census period. The natural increase during the latter period was slightly over two millions. From this it would appear that, since last census was taken, the rate of increase of the population has been reduced to half the rate prevailing during the corresponding years of the preceding inter-census period. In a season such as that under report when, instead of the births being in excess of the deaths, there is on the contrary an excess of 438,645 deaths over births, the regularity of the increments to the population, which can be counted on with some approach to certainty in temperate climates, is violently interrupted in a country like India. A similar but more marked interruption took place in 1894, when, owing chiefly to cholera and fever, the mortality considerably exceeded that recorded for the year under report. Pestilence in one of these two years and famine in the other have mainly been concerned in retarding the increase of the population as compared with its increase in the period 1881–87. But although increase in the number of deaths was mainly responsible in bringing about this retardation, it was assisted by decrease in the number of births. In the year under report the number of children born was the smallest hitherto recorded, at all events the smallest recorded in the table given on page 2, which includes the period beginning with 1881 and ending with 1897. On the other hand, the number of births in 1894 was, with one exception, the highest recorded since last census. The birth-rate of a year being mostly governed by the conditions prevailing during the previous year; and the previous year, 1893, having been one of the healthiest on record, the birth-rate of 1894, although itself an exceptionally unhealthy year, was a high one. The influence of the unhealthiness of 1894 is to be looked for, not in its own record of births but in the record of the year succeeding it. In 1895 the birth-rate fell from 39·70 in the preceding year to 34·90 per thousand of population. The diminished birth-rate of the year under report combined with its high death-rate to retard the natural increase of the population to the extent of not very far short of half a million. Whilst the birth-rate fell from 35·40 in the previous year to 31·10, the death-rate at the same time rose from 33·32 to 40·46 per thousand of population. These rates for the Province as a whole give, however, but an imperfect idea of the effects of famine on fecundity and mortality on the population of the districts which were the chief sufferers. In the Hamirpur district, for example, the death-rate rose from a mean ratio of 39·05 during the previous five years to 61·83; and in Jalaun from 35·57 to 58·92. At the same time the birth-rate of Hamirpur district fell from a mean during the previous five years of 38·23 to 18·38; and that of Jalaun from 39·76 to 19·26. In the Hamirpur district there were 10,015 births registered against 31,887 deaths, or not quite one of the former to three of the latter; whilst in Jalaun, there were 11,403 births to 23,667 deaths registered, or less than one birth to every two deaths. In the other districts mentioned in paragraph 10 of the Report the effects were more or less similar; but of these districts, two, with death-rates of over 55 per mille of population, did not belong to the list of

those declared to be famine-stricken. The high mortality in these two was due chiefly to malarious fever "of a severe and persistent type." In neither of the two, however, did the excess of deaths over births come up to that recorded in the famine-stricken districts. In 76 of the 104 municipalities the deaths exceeded the number of births; and the urban death-rate, as a whole, was greatly higher than that recorded in rural tracts, the former having been 48·55 as compared with39·86 in the latter. In most of the municipal towns with high death-rates "the explanation lies in the fact that they were "the situation of poor-houses to which the beggars, lepers, and the generally submerged portion of "the population came too frequently only to die." The endeavour made to differentiate the causes of death by a professional agency led to the verification of 15,116 cases. Out of this number, only 1,587 deaths are attributed to remittent and intermittent fevers; but 3,345 are attributed to "other fevers." Even when the deaths from fevers of every kind are added together they form less than a third of the total deaths. On the other hand, the deaths diagnosed as due to bowel-complaints numbered 3,706 and formed nearly a fourth of the total; whereas in the returns for the Province, whilst the death-rate attributed to fever is recorded to have been 31·21, that attributed to dysentery and diarrhæa was only 1·25 per mille of population. From this it may be inferred that, whilst the reporting agencies greatly over-state the number of deaths due to fever, they greatly under-state those due to bowel complaints; a conclusion at which many medical and sanitary officers have arrived in other provinces. It is not to be expected that the ordinary village watchman can do much towards differentiating diseases, but what he can do he does well. Although he can generally neither read nor write, the accuracy with which he reports the births and deaths occurring within his beat is put beyond question by the results of the testing of the registration by local revenue, civil and police officers, and by members of District Boards. An examination by these agents of 148,015 entries of births went to show that a percentage of 2·79 had been omitted; and an examination of 179,149 entries of deaths, that a percentage of 2·43 was omitted. "The approximation of these results to those "of former years," writes Dr. Thomson, "may be held to point to the general accuracy of the returns." Verification by the vaccination staff was also, as in former years, extensively carried out. The percentage of omissions recorded to have been detected by this agency was small. In his previous report the Sanitary Commissioner explained what is probably the real cause of the small number of omissions recorded by vaccinators. As Dr. Thomson, in a previous report, stated: "The collection "of vital statistics for this vast area and population is carried on by the village watchman, the only "method possible with any regard to reasonable economy, and, upon the whole, it is wonderfully "well performed. Probably it is one of the most efficient reporting agencies, at the price, in "the world."

2. *History of Chief Diseases.*—The death-rate from *Cholera* was only equal to a ratio of 0·94 per thousand of population, as compared with 1·47 in the previous year, and with 2·16, the average for the five years preceding the year under report. This comparative immunity from cholera in a year of widespread famine and high prices is not a little remarkable. In our memorandum on the Sanitary Report for Bengal for the same year we noted that in Bihar, which was the most severely famine-stricken part of the Province, the mortality due to cholera was less than half that in the preceding year, and by far the lowest recorded in any division of Bengal. From this we ventured to draw the conclusion that there was no necessary connection between the existence of famine and the prevalence of cholera. The comparative freedom of the North-Western Provinces from cholera would seem to lend some support to such a conclusion. On the other hand, it cannot be overlooked that, under similar conditions of famine, the result was very different in other provinces. In Bombay the cholera death-rate was 3·03, in Madras 4·4, and in the Central Provinces 6·01 per thousand of population, as compared with only 0·94 in the North-Western Provinces and Oudh. Taking into account the vast numbers employed on relief works, and the privations which they must have endured inthe hot and rainy seasons, the immunity from cholera which the latter figures indicate is noteworthy. Onlyonce during the preceding eight years has it been as low as it has been during this year, when the conditions seemed favourable to its epidemic prevalence. But the measures adopted for dealing with outbreaks of the disease cannot be ignored as factors in bringing about this result. "It was mentioned in last report," writes the Sanitary Commissioner, "that in the careful preservation of the purity of the water-supply, the prompt "removal of the people from the infected area, and the breaking up of large bodies of people into "smaller units, lay the best prospect of coping with outbreaks of epidemic disease on relief works. "The experience of the past year has fully borne out this anticipation. Over and over again "cholera in an epidemic form has appeared on the works, but in all cases the procedure adopted "has succeeded in speedily extinguishing the outbreak." In short, the method of dealing with an outbreak of cholera in cantonments was modified and adapted to suit the different conditions prevailing on relief works, with the result that the soundness of the principle underlying the method received a fresh illustration and confirmation. Dr. Thomson thinks there is no doubt as to the utility of the disinfection of wells with permanganate of potash; but on this point there is still some difference of opinion. The Deputy Sanitary Commissioner, Dr. Chaytor-White, in describing the outbreak of a virulent form of cholera amongst the relief workers in the Allahabad district, says the Superintending Engineer spoke very highly of the effect of potassium permanganate and was inclined to attribute the decline of the epidemic to its use. Dr. Chaytor-White adds:—"The result, "however, is not sufficiently convincing to enable one to formulate a definite answer to the "question as to whether it was really a case of *post hoc* or *propter hoc*. Later experiments with "permanganate have shown anything but convincing results, and the matter may be said to be "still *sub judice*."

3. *Small-pox* accounted for 87,127 deaths, or more than twice as many as in the preceding year. The death-rate per mille of population was the highest caused by small-pox in the combined provinces since 1884. The Sanitary Commissioner suggests that the explanation of this increase in the year under report "is possibly to be found in the peculiar climatic conditions prevailing." These conditions may have had some influence, and the diffusion of infection may have been aided by the collection of people on the relief works, as well as by the wandering about the country in quest of employment and food of destitute persons, always a feature of a famine year; but more

potent than any or all of those causes was doubtless the insufficient protection of the population by vaccination. Of the eight districts which are stated in paragraph 43 to have suffered most severely out of the 48 which belong to the combined provinces, the 12 districts of Oudh furnished half. Vaccination in Oudh has lagged far behind vaccination in the North-Western Provinces; and to this cause is almost certainly due the fact that of its 12 districts half of them show small-pox death-rates above the provincial average; whilst in the 36 districts of the North-Western Provinces there are only 11 with rates above the provincial rate. The year was an unfortunate one for vaccination. The number of successful primary vaccinations fell from 1,308,941 in the previous year to 1,182,395; and the successful re-vaccinations from 52,421 in the former to 41,934 in the latter year. The percentage of successful cases in primary vaccination, in which the result was known, fell at the same time from 94·65 to 93·74 One of the reasons given to account for the decrease in the year's work was the low birth-rate. There were 201,440 fewer births registered than in the previous year. It is stated, also, that the reduced condition of the children rendered many unfit for operation. Of the adverse influence of these two causes there can be no question; but the prevalence of small-pox in 1896 and 1897, given as a third reason, except in so far as it reduced the number of persons in need of protection by vaccination, might have been expected to encourage people to resort for protection to vaccination, and especially to re-vaccination. The deputation of vaccinators on plague duty would, no doubt, dislocate their arrangements for the performance of their proper work, and would materially lower their season's record. Referring to Statement No. I. of the Vaccination Report for 1897, it is seen that the number of children under one year of age who were successfully vaccinated was 551,113. The number of births registered in 1897 was 1,458,947, and the number of children who died before completing their first year was 425,051, leaving available for vaccination 1,033,896. According to this calculation little more than half the number of children available were successfully vaccinated. Until the number of successfully vaccinated children under one year of age approximates more nearly to the number available for vaccination, the cessation of recurring small-pox epidemics need not be looked for. In the Bombay Presidency, in the year under report, 84·73 per cent. of the children under one year of age were successfully vaccinated, and the small-pox mortality for 1897 was equal to a ratio of only 0·20.

4. *Fever* was credited with 1,463,716 deaths, giving a death-rate per thousand of population of 31·21, as compared with 25·7 in the previous year. But there can be no doubt that this ratio is greatly enhanced at the expense of other diseases. Judging from the proportion of deaths certified as due to fevers by the independent medical practitioners mentioned in paragraph 22 of the Report, it may be inferred that, whilst the number of fever deaths would be greatly reduced by accurate diagnosis, the number caused by *Dysentery and Diarrhœa* would be correspondingly increased. In a year during which high prices and famine reduced large numbers of people to eke out a scanty dietary with unsuitable and unwholesome articles of food, the conditions known to be specially favourable to the causation of bowel complaints were unusually prevalent, and the 58,822 deaths attributed to these diseases represent probably but a portion of the real number. Of the fever which prevailed, Dr. Thomson remarks that "it is unsafe to definitely say more than that malarial " fever was of a severe type, and that the people generally were, from a reduced condition of health, " less able than usual to withstand it."

5. An interesting account is given of the campaign carried on against *Plague*, which effected an entrance into the Province, it is said, from Sind. The measures adopted with the object of preventing the disease from securing a permanent footing were successful. The entire number of deaths recorded as due to it from the time of detection of the first case on the 8th April until the end of the year was 73. Early detection and prompt segregation of first cases, followed by evacuation and disinfection of the houses in which the cases occurred, formed an essential part of the programme adopted with the object of circumscribing and stamping out the disease.

6. *Sanitary Works.*—Although, as stated in the Government Review of the Report, funds were but little available for expenditure directly on sanitary objects, the condition of a large number of villages was improved by the works undertaken in connection with famine relief, and in towns, apart from the large schemes still in hand, much progress was made in raising the standard of sanitation. At Benares progress is being made towards the completion of the sewerage of the city, and at Allahabad the extension of the filtered water-supply to Daraganj, near which the great religious fairs are held at the junction of the Ganges and Jumna Rivers, was taken in hand. Both works are of the utmost importance in their bearing on the health conditions of two cities subjected to special danger from importation into them of disease by pilgrims from all parts of India. Difficulties have arisen in connection with the waterworks of several of the large towns; but these are only such as might be expected to occur whilst waterwork schemes are still comparatively new to the country, and have already been, or are being, overcome. In these, as in the other Indian provinces, the fear of plague invasion has doubtless given a wholesome stimulus to sanitation. The Sanitary Commissioner writes :—" The sanitary condition of the principal centres of population in these provinces has received " an amount of attention which it has certainly never received before. It was part of the policy of " the Government for prevention of plague to render such centres as little likely as possible to prove " suitable breeding grounds for the disease." The difficulty, ever present in India, of counteracting the corruption of the official underling, came strongly into evidence in dealing with the plague crisis. " It may be said that the prevention of the abuses of power by lower subordinate officials has been " the greatest difficulty experienced in the course of the plague operations in these Provinces." More than a difficulty, it is a danger which can never be overlooked where the conduct of operations, such as those which may be called for in combating plague, gives opportunities to dishonest subordinates for the practice of oppression. In a valuable memorandum by the Sanitary Commissioner, given as an Appendix to the Report, it is satisfactory to read regarding the disposal of the sewage and refuse of towns :—" Water carriage and incineration hardly exist in these Provinces." The return to the soil of what has been taken from the soil is generally accepted as a sound principle; and sanitarians in most countries are coming to deprecate the wasteful discharge of the sewage of towns into rivers or the sea, as well as the destruction by fire of refuse which should enrich the soil. The new

Annual Form XI. appended to the Report, if revised from year to year, will form a useful record of the progress being made in the sanitary improvement of the 104 municipalities of these provinces.

7. Briefly, the year was a trying one from a health point of view. The premature cessation of the rains in 1896 caused failure of the crops. High prices and famine resulted in severe and wide-spread distress. The climatic features of the season were not more than ordinarily unfavourable to health, and, after the setting in of an abundant and seasonable monsoon, good harvests followed, with speedy restoration of prosperity. Immediately succeeding a season of drought and privation, the year under report showed a marked decrease in the birth-rate, and a still more marked increase in the death-rate. The deaths exceeded the births in number by 438,645. Enfeebled by prolonged privation, many succumbed to complaints from which, in ordinary years, they would have recovered. Contrary to what might have been anticipated, cholera was less fatal than during the previous year, and the death-rate due to it was lower than the mean for the previous five years. In accounting for so satisfactory a result, the measures adopted with the object of preventing outbreaks of the disease, and cutting them short when prevention failed, should not be overlooked. Small-pox carried off 87,127 persons. The Sanitary Commissioner suggests that the climatic character of the year may have been concerned in exciting so severe an epidemic. To some extent the suggestion may be well-founded; yet there can be no room for doubt that the main cause was the insufficient protection of the population by vaccination. Approximately, half a million of the children under one year of age available for vaccination were not vaccinated. Until the number of infants successfully vaccinated more nearly approaches the number of infants available for vaccination, the periodical recurrence of small-pox epidemics is not to be looked for. Malarial fever of a severe type caused a high mortality; but it is certain that large numbers of deaths attributed to fevers were really due to other diseases. Dysentery and diarrhœa are recorded to have caused only 52,822 deaths; and reasons are given for believing that the actual number of deaths due to these diseases, in a season when high prices and scarcity drove many of the poor to eke out their dietary by unwholesome articles of food, was much greater. Although plague effected an entrance into the Province, the measures adopted with the object of preventing its spread fortunately proved successful. New sanitary works on an extensive scale could not have been undertaken during a year in which the resources of the State and of Municipalities were severely strained in the struggle with famine and pestilence; but the fear of a plague invasion gave a healthy stimulus to the cleansing of towns, and the Sanitary Commissioner thinks the sanitary state of these has had a greater amount of attention bestowed upon it than it has ever had before. Even from the calamities of the year some compensating benefits have been thus reaped. As the Sanitary Commissioner concludes his Report by observing: "The mortality, though "far below what might have been reasonably expected, has been in the nature of things high. "Regrettable as this unavoidable mortality is, there are circumstances from which the social economist "may glean satisfaction. A low birth-rate means fewer mouths to fill, and consequent better "nourishment of the children; while the expectation of life may be expected to increase in a "population from which the diseased and pauper elements have been so largely eliminated."

9th June 1899.

No. 4.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Punjab for 1897.

The volume containing the Report, its Appendices, Map and Government review is of little more than half the bulk of its predecessors. This decrease in size is owing mainly to the substitution of the present Annual Form II., covering six pages, for that previously in use covering upwards of eighty. The Sanitary Commissioner's Report, contained in 24 pages, is concise and deals only with what is essential. The year was a fairly healthy one. Like other provinces, the Punjab had its famine areas; but these were of limited extent, and early and effectual measures for the relief of distress were adopted. The average rainfall for the province was considerably less during each quarter of the year than the average for the corresponding quarters of the previous ten years. Prices of grain ruled high in the Punjab, as they did all over India; but although relief operations were undertaken over 12,000 square miles with a population of 3¼ millions, famine only reached the acute stage in one district.

2. *Vital Statistics.*—Again, the birth-rate of the Punjab was higher than that recorded in any other province of India. The Sanitary Commissioner attributes this, in part at least, to the system of check of registration by the vaccinators and divisional inspectors. It appears from the tables given in paragraphs 28 and 29 that out of a total number of 874,623 entries of births made during the year, the very great number of 608,714 were checked by the vaccinators and divisional inspectors; and that 10,792 births of males and 10,144 births of females were discovered by these agents to have been omitted from the registers. At the same time, 198,150 entries of deaths of males and 173,608 of females were checked, with the result that 4,465 deaths of the former and 4,478 of the latter were discovered to have been omitted. The testing by the divisional inspectors seems to have been by far the most thorough, judging by the number of omissions discovered by them in proportion to the number of entries examined. To this systematic check of the village watchmen's books there can be no doubt that Dr. Roe is justified in assigning in great part the improvement which has been, and is being, made in the registration of vital statistics in the Punjab. By way of contrast, the statement of the results of inspection carried out by tahsildars and assistant tahsildars may be put

side by side with the results recorded by divisional inspectors. Whilst the former officials detected only 1,725 omissions of births of males and 1,620 of females in 15,562 villages, the divisional inspectors detected 4,948 omissions of births of males and 4,873 of females in 4,746 villages. As the Sanitary Commissioner remarks of the testing of registers by the former officials, "their work "in this respect was far from satisfactory." And this need not be wondered at: officers such as tahsildars and their assistants, with other multifarious duties to attend to, cannot devote the time necessary to thoroughly test the registration of births and deaths entry by entry. In calculating the total number of entries tested by the several agencies, the error must not be made of concluding that each entry, recorded as tested, represents a separate birth or death. Although not so stated, it may be inferred that the same entries were tested in some of the villages by more than one of the several inspecting agents. If this inference is correct, the total combined number of entries returned as examined by the several inspecting agents would, of course, exceed the actual number of entries of births and deaths, seeing that some of these had been tested and counted more than once. Adding up the total number of villages inspected, according to the tables given in paragraphs 27, 28, and 29, it is found that they aggregate 52,295. But there are only 37,602 villages in the province, and therefore 14,693 villages must have been inspected more than once. It would thus appear that, the same villages having in some cases been inspected more than once, the same entries in the watchmen's registers may likewise have been inspected more than once. This, however, although probable, does not necessarily follow.

3. The number of births was less than the number in the previous year by 10,069, but exceeded the deaths by nearly a quarter of a million, or 11·5 per thousand of the population. From this it appears that the localised prevalence of famine in the Punjab did not sensibly check the natural increase of the population, which was, for the province as a whole, the same as in the preceding year. But where acute famine existed, as in Hissar, the only district in which it did exist, the results for the province were reversed; the deaths exceeded the births, and the population, instead of increasing, considerably decreased. There was in Hissar district an excess of 8,883 deaths over births. Scarcity acted here in both directions, reducing the birth-rate from a mean of 43·4 during the previous five years to 33·9 during the year under report; and raising the death-rate from a mean of 32·1 during the previous five years to 45·3. Although registration of births is making progress in the frontier districts it is still very backward in certain of them, such as Peshawar and Hazara. In these latter, the registration of births, of female children more especially, is defective. In one rural circle the ratio of male to female births was recorded to be 189·3 of the former to 100 of the latter; and in other three circles the ratios exceeded 140 to 100, the ratio for the Punjab as a whole having been 110·5 to 100.

4. The *death-rate* for the year, which in spite of high prices and local famine was a healthy one was 31·05 per thousand of population as compared with 31·53 in the previous year. It has already been noted that the birth-rate was the highest recorded in any province of India. A high birth-rate is the ordinary accompaniment of a high death-rate; but such was not the case in the Punjab, in which the death-rate was 31·05 as compared with 32·94 in Bengal, 39·84 in Bombay, 40·46 in the North-Western Provinces and Oudh, 50·61 in Assam, and 69·34 in the Central Provinces. The death-rate recorded in the Madras Presidency was only 25·4; but seeing that famine in an acute form prevailed over extensive areas of that province, this rate, although useful for comparison with the rate of 20·6 recorded in itself in the preceding year, can hardly be regarded as even approximately representing the actual rate. The district of the Punjab which returned the highest death-rate was Dera Ismail Khan. In this the rate was 50·2 as compared with 45·31 in Hissar, although, unlike the latter, it did not suffer from famine. Turning to pages vi. and vii. of the Appendix to the Sanitary Report, it will be seen that "the principal sanitary defects" recorded for this district would not suggest unhealthiness. Of the drainage it is stated that it was "good and "satisfactory," of defects in water-supply that there were "none," that conservancy was "improving"; whilst the "measures taken for sanitary improvement of district" were "some wells "cleaned out and parapets made."

5. To the *Chief Diseases* hitherto dealt with, a new one has been added. Plague, according to the Sanitary Commissioner's account, was introduced into the province by a Brahmin, who had been on a pilgrimage to Hardwar and returned on the 29th of April to his village in the Jullundur district, where he died after a few days' illness. Whilst admitting that the disease may have been introduced in the way described, the Lieutenant-Governor does not think this certain, and adds:—"it seems "quite as probable that the Rawals, who have a home in Khatkar Kalan and who are notorious "wanderers, may have brought plague with them from Poona or Bombay." It was not until the month of October that the disease declared itself in epidemic form. Up to the close of the year there were altogether five villages attacked, four in the Jullundur and one in the Hoshiarpur district. The total number of seizures was 302 and of deaths 175. The village of Khatkar Kalan, when the disease was officially announced to be plague, had a cordon placed round it, with the view, doubtless, of isolating it. Whatever may have been the effect of the cordon on the progress of the epidemic, it is certain that the effect of the next step taken was marked. "During the following "week the entire population of the village were turned out into camp, and hutted within the "village area." The efficiency of this method of dealing with plague has from the first been amply demonstrated; and science, although usefully supplementing it, has so far failed to provide a method of treatment which in point of efficacy has superseded it. Unfortunately, it cannot always be carried out as it is desirable that it should be. In the case of a great city like Bombay thorough evacuation would obviously be impracticable. Where, however, it is practicable, and can be carried out early and in a thorough manner, it still holds its place as the most effectual means yet tried of arresting the disease.

6. *Cholera* was confined almost entirely to Hissar, the one district of the province in which acute famine prevailed. Of the total number of 622 deaths caused by it in the entire province, 538 occurred in Hissar alone. As showing the limited area affected, it is stated that cases of the disease were reported in only 31 out of the 37,602 villages in the province. The water-supply in some cases,

and importation of infection by travellers in others, were usually credited with causing the outbreaks; but the evidence in support of these statements is too meagre and vague to be very convincing.

7. *Small-pox*, which was so prevalent and fatal last year, when it swept off 45,084 persons, caused 16,077 deaths in the year under report. Having now killed, or left protected against further attack, most of those who had not already had the disease or been vaccinated, small-pox may, in accordance with its usual behaviour, probably remain more or less in abeyance until a further re-accumulation of susceptible material has had time to take place. The fatal epidemic of last year should serve as a warning against remaining satisfied with the amount of protection hitherto being conferred under the system of vaccination in force. As the Sanitary Commissioner points out, the death-rate from small-pox in a large number of municipal towns was excessive, "which indicates clearly that "vaccination work in them is neglected." Unfortunately, the work of the Vaccination Department for the year 1897–98 shows, instead of an increase, a serious decrease of no fewer than 56,922 cases. According to Statement No. I. of the Vaccination Report, the number of children under one year of age successfully vaccinated was 475,929. There were 874,623 births recorded in 1897; and the deaths of children under one year of age numbered 202,577. Deducting the latter figures from the former, there would remain available for vaccination 672,046. Of these, 475,929 were successfully vaccinated, leaving an unprotected residuum of 196,117. Even when allowance is made for a certain proportion unfit for vaccination, on account of feebleness or illness of some kind, it will be plain that, with nearly 200,000 children remaining unvaccinated of those born in a single year, the danger of a recurrence of a small-pox epidemic at no very distant period is more than a probability. With so many infants unprotected by vaccination, the record of 213,717 cases of re-vaccination seems to suggest that it might have been preferable, had some of the attention devoted to re-vaccination been given to increasing the amount of primary vaccination. The Sanitary Commissioner writes: "The Civil Surgeons attribute the great falling-off in the number of primary "vaccinations chiefly to the high mortality among children during the year, and partly to the failure "of lymph and carelessness of the vaccination staff." It has, however, been shown that, when the number of children under one year of age who died is deducted from the number born, there remained nearly 200,000 available for vaccination, but who were not vaccinated. The quality of the lymph used is of vital importance. Human lymph in primary vaccination gave a per-centage of 98·2 successful cases, and animal lymph of 99·3, whilst vaseline lymph gave a per-centage of only 94·3. On the other hand, vaseline lymph gave the second highest per-centage of success in re-vaccination, a per-centage (75·6) which suggests that it did not fail to produce some form of local irritation, which the vaccinators considered themselves justified in entering in their registers as "successful." We have more than once expressed some scepticism when these high per-centages of successful cases in re-vaccination have come before us. The opinion of an officer of great experience, the Sanitary Commissioner of the Hyderabad Assigned Districts, noted in our memorandum on his report, is deserving of consideration in this connection.

8. Fevers and bowel complaints were somewhat more fatal than in the previous year. The ratio of deaths *per mille* of population from fevers was 20·57, as compared with 19·15 in 1896; and the ratio from dysentery and diarrhœa 0·77. In Hissar, the one district in which acute famine prevailed, the ratio of deaths due to fevers was 34·23, and from bowel complaints 2·02. The latter ratio was not reached in any other district of the province; but the fever death-rate was exceeded in Dera Ismail Khan and in Muzaffargarh, districts in which famine conditions did not prevail. The fevers were of malarial type. Hitherto, the sale of quinine through Postal Agency in rural tracts with the object of combating fever has not in the Punjab been a success; but the Lieutenant-Governor thinks it should not be abandoned without further trial, and proposes to continue it under modified conditions which it is hoped may render it more successful.

9. *Sanitary Works.*—Some progress was made in providing and improving water-supplies for towns. Under this head an expenditure of considerably over two lakhs of rupees was incurred; whilst upwards of one lakh was expended on drainage works. With the view of encouraging village sanitation, the Lieutenant-Governor desired that the experiment might be tried of a District Board offering to pay a considerable fraction of the revenue demand of the one village in each tahsil which showed the best results during the current year (1898), the adjudicators being the Deputy Commissioner and the Civil Surgeon aided by one or two native officials. The Sanitary Commissioner is asked to bear in mind that a full report of the action taken and its results is to be submitted as early in the year 1899 as possible. The experiment seems promising. If the people can be induced by the hope of reward to keep their villages clean, the introduction of legislative measures followed by punitive proceedings, with their attendant opportunities for oppression and extortion by underlings, would be avoided. Only one meeting of the Sanitary Board was held during the year at Simla, when papers regarding the excessive death-rate from fevers and other kindred matters were considered.

10. Briefly, the year was on the whole a healthy one. Although high prices prevailed in the Punjab as in other parts of India, acute famine was confined to the one district of Hissar. In this district the effects of famine were marked by a diminished birth-rate and a greatly increased death-rate—the deaths exceeding the births by 11·4 per thousand of population; whilst for the province as a whole the births exceeded the deaths by 11·5. Registration of vital statistics, as judged by results, is probably as efficiently carried out as in any other province of India. Plague made its appearance in the Punjab, and by the end of the year had attacked five villages and proved fatal to 175 of a total number of 302 persons seized with it. The mode of the introduction of the disease is not altogether certain. The efficacy of early and complete evacuation of the infected villages in arresting the disease was clearly demonstrated. Cholera was mostly confined to the famine-stricken district of Hissar, in which it proved fatal to 538 persons out of a total number of 622 who died of it in the province. Small-pox, which was excessively fatal during the preceding year, was credited with 16,077 deaths in the year under report. Unfortunately, a serious decrease

in vaccination work is recorded for the year 1897–98. This decrease is attributed, in part, by Civil Surgeons to the great mortality amongst children ; but when the recorded deaths of children under one year of age are deducted from the recorded births, it is seen that the remaining number available for vaccination exceeded the number successfully vaccinated by nearly two hundred thousand. With so large a residuum of infants in need of vaccination, the wisdom of devoting so much attention to re-vaccination seems to be open to question. There were 213,717 cases of re-vaccination. Fevers and bowel complaints were somewhat more fatal than during the previous year. The experiment for placing quinine within easy reach of the people for purchase is to be continued under modified conditions. Sanitary works made some progress. The Lieutenant-Governor desires to try the effect of offering rewards to induce villagers to improve the sanitary state of their villages.

9th June 1899.

No. 5.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Burma for 1897.

In Burma, as in India, failure of the rains of 1896 was followed in part of the province by scarcity and famine. The tract of country affected lies in Upper Burma, in which arrangements for the systematic collection of vital statistics do not yet exist. The effect of the famine on the health of the population cannot therefore be ascertained with any approach to certainty. The relief afforded to the famine-stricken districts by the State was so prompt that the mortality directly due to privation was probably not great. Under the pressure of scarcity, more than a third of the population of the affected tract migrated to Lower Burma, where they found employment and relief. One result of this famine has been to draw the attention of the Government to the urgent need for the extension into Upper Burma of the system of registration of births and deaths in force in Lower Burma, in order that, in the words of the Lieutenant-Governor, "there may be due "warning of the approach of scarcity, and that the severity of such calamities may be gauged." The Government proposes to introduce the system of registering deaths in the more civilized areas of Upper Burma, with effect from the 1st January 1899. "The registration of births will not be "attempted." But, as no separate agency is needed for the registration of births, the same agents in Lower Burma registering both births and deaths, it seems a pity that a commencement should not be made of registration in Upper Burma on the same complete system as that which is making so satisfactory progress in Lower Burma. The inclusion of births would add comparatively little to either the labour or cost of registration of vital statistics ; whilst it would almost, or altogether, double their value. In the opinion of the Chief Commissioner of the Central Provinces, quoted in another memorandum, a reduction of the birth-rate in a tract of country may be accepted "as almost "conclusive evidence of the prevalence of pressure on the labouring population."

2. Except in Mandalay and three other municipal towns, vital statistics are not as yet recorded in Upper Burma, and even in Lower Burma there are still districts and parts of districts in which registration is not in force. The portion of Lower Burma for which vital statistics are available contains a population, according to the last census, of 4,514,773. Calculated on this number, the *birth-rate* for the year was 31·82 *per mille*. During the preceding year the rate was 32·27, or a fraction higher. No doubt the real birth-rate is considerably higher than the recorded birth-rate. This is shown by the results of the inspections carried out in towns and districts of the province. These inspections, to judge of them from the tabulated statement on pages 2 and 3, were carried out only to a very limited extent, and in some cases with no great thoroughness ; but what of evidence they afford goes to support the conclusion that many births and some, though fewer, deaths remain unregistered. Revised rules relating to registration are published in an Appendix to the Report ; and, in the opinion of the Lieutenant-Governor, appear now to be "theoretically perfect." The best proof of the improvement which is being effected in the working of the rules is the steady decrease in the numbers of births and deaths which are omitted from the registers. From a record of only 18·45 births per thousand of population in 1873, a rate of 31·82 is recorded in the year under report. During the last six years the improvement has been more steady and rapid than in preceding years. The quarterly review by the Sanitary Commissioner of the provincial statistics published in the official Gazette will be useful in calling attention to returns of births and deaths which markedly deviate from normal. Commissioners are enjoined by the Government to make full inquiry into the causes of such deviations, and to adopt the proper remedy where the registration is found to be faulty. The differences between the birth-rates recorded in some towns are remarkable. Rangoon shows a ratio of 17·61, and Bassein a ratio of 35·19, *per mille* of population. In the case of Rangoon, as in the case of Bombay, the explanation given of the low birth-rate is the small proportion of females to males in the population. According to class, the birth-rate varies still more widely. Whilst amongst Burmans or Buddhists the recorded rate is 33·47, it is only 8·57 amongst Hindus.

3. The *deaths* registered were equal to a rate of 26·26 *per mille* of population, against 23·63 in the previous year and a mean of 22·27 for the past five years. The rate has continued to increase from 15·22 in 1873 to 26·26 in the year under report. In urban areas it was 32·34, as compared with only 25·33 in rural areas. These rates are considerably higher than those recorded in the preceding year, and than the mean of the preceding quinquennium. The increase was chiefly due to cholera and "other causes," but doubtless also in part to improvement in registration. Amongst children

under one year of age the increase was marked. The death-rate amongst male children of this age was 269·24 *per mille*, as compared with 235·90 in the previous year; and amongst female children 188·24, as compared with 169·44. According to class, the highest death-rate took place among Hindus. It has already been seen that amongst these, the lowest birth-rate was also recorded. The Sanitary Commissioner explains that the Hindu population of 141,526 is chiefly made up of coolies "who from the nature of their occupation are specially liable to early breakdown." It is presumed that these coolies are chiefly males who have emigrated from India without taking their wives with them. If so, this would help to account for the almost incredibly low birth-rate of 8·57 recorded for the Hindu population. On page 10 of the Report a useful statement is given of the meteorological records for the year, of the mortality from four of the chief diseases, and of the average price of food-grains in the four districts of Rangoon, Toungoo, Tavoy, and Mergui. "According to this statement," writes the Sanitary Commissioner, "the districts with the least "mortality have a more equable temperature, a northerly wind, a much greater rainfall, and a "cheaper staple food-grain; whilst the districts in which the mortality was highest are characterised "by a less stable climate, southerly wind, a much smaller rainfall, and higher priced grain. But "considering the fact that heavy rainfall is an undoubted cause of sickness, and that the range of "temperature in the different groups is not a striking feature, the inference is inevitable that faulty "registration rather than meteorological conditions were responsible for the apparent comparative "healthiness of Tavoy and Mergui."

4. *Chief Diseases.*—The mortality from *Cholera* was the highest recorded since 1888. The disease was wide-spread, affecting all, except three, of the districts of Lower Burma, and prevailing throughout the year, although most fatal in March, April, May, and July. As the Sanitary Commissioner says, it is almost impossible to trace the history of an epidemic of the disease as regards its origin and mode of spread in a country like Burma, where cholera is ever present in one form or another. The truth of this is exemplified by the account given, in paragraph 33, of the variety of conclusions arrived at by District Medical Officers. One is unable to state whether the disease was imported or originated locally; another asserts that it was brought into his own district from another; in two districts the disease was ascribed to the use of river water; whilst the Health Officer of Rangoon attributes it there to the use of tank water, and states that changing the water-supply in the case of two outbreaks promptly checked the epidemic. In six districts no cause could be traced to account for the appearance in them of the disease; whilst in a seventh the influx of coolies from Chittagong is credited with its introduction and spread. In short, another year's observation of cholera in Burma has added little of value to our knowledge of its origin and mode of propagation.

5. *Small-pox* was accountable for 1,950 deaths, or a ratio of 0·43 per thousand of population, and was somewhat more fatal than during either of the three previous years. Of the deaths 19 per cent. occurred amongst infants under one year of age, 46 per cent. amongst children between one and 12 years, and the remaining 35 per cent. among persons over 12 years. There seems to be a consensus of opinion that in Burma the practice of inoculation is responsible for the majority of the outbreaks of small-pox. Of the 181 deaths caused by the disease in the towns of the province, no fewer than 137 occurred in Rangoon and Moulmein. In the case of both of these towns, the introduction and spread of small-pox are attributed by the Health Officers to the unprotected Coringee coolie emigrants. It has been found difficult to put a stop to surreptitious inoculation in countries in which it has been practised from time immemorial, and it will no doubt be difficult to stop it in Burma until the people come to recognise that vaccination, the substitute for it, is equally effectual as a protection against small-pox, and at the same time simpler, attended with less suffering to the person operated on, and without risk to this person's neighbours. The circumstance that vaccination may be had for nothing, whilst inoculation is attended with considerable expense, would give the preference to the former in the case of the poor; but those able to pay for it would probably still prefer inoculation, consecrated as it is by ancient custom and performed with mysterious religious rites. As regards the introduction of small-pox by immigrant coolies into Rangoon, the Lieutenant-Governor believes the danger "will "be sufficiently guarded against if power is taken to vaccinate unprotected persons on board ship on "which small-pox has occurred and unprotected inmates of a lodging-house or a cooly barrack, and "also to serve notice upon any unprotected person to be vaccinated within seven days. Provision to "this extent has accordingly been made in the new Vaccination Bill, which it is intended to introduce "at the next meeting of the Legislative Council." Taking, however, into consideration the fact that the period of incubation of small-pox is from 10 to 16 days, and that the voyage from India to Rangoon is greatly less, it might well happen that coolies infected before embarkation would not develop the disease until some time after landing in Rangoon. Unless such persons were detained under observation in Rangoon, they might become the means of introducing the disease amongst the inhabitants, or of carrying it with them and spreading it in the country beyond. If recruitment were not discouraged thereby, it would seem safer to insist on coolie emigrants being vaccinated or re-vaccinated before embarkation for Burma. Quoting from the Resolution of Government on the Annual Report on Vaccination for 1897–98 :—"The vital statistics of 1897 show that the mortality from small-pox was greatest in districts near the capital." The inference is clear, and in accord with the opinions expressed by the Health Officers of Moulmein and Rangoon, as to the part played by immigrant coolies from India in the importation and dissemination of small-pox. In the present Report, the vaccination returns for Upper Burma, instead of being shown separately as heretofore, are, in accordance with the instructions of Government, incorporated with those for Lower Burma. The total number vaccinated during the official year 1897–98 was 421,786, as compared with 414,845 in the previous year; whilst the percentage of successful cases at the same time increased from 92·43 to 94·56 in primary cases. Of successful cases of re-vaccination the percentage likewise increased from 59·50 in 1896–97 to 61·38 in the year under report. The ratio per thousand of population successfully vaccinated rose from 46 to 48. These figures show that satisfactory progress is being made; but, as the Sanitary Commissioner remarks :—"Infant vaccination, though showing improvement, falls far short of the estimated births." The increase in the number of children of this age vaccinated over the number vaccinated in the preceding year was 6,494. An unfavourable feature in

the season's work is its continued decrease in Rangoon: since 1894–95 vaccination work has steadily declined both in quantity and quality. The fatality of small-pox in that city is probably more than a coincidence of this decline. The Sanitary Commissioner gives a very useful table at page 4 of the Notes on the Statistics of Vaccination in Burma for the year. In this table are shown the number of births in municipal towns, the number of deaths amongst children under one year, the number of survivals available for vaccination, and the number of children under one year successfully vaccinated. This return might be adopted with advantage in the provinces of India.

6. *Fever* mortality was about the same as during the preceding year. From a total of 19,964 deaths credited to fever in 1873, the number has increased to 51,752 in the year under report; but this large increase is doubtless rather the result of improved registration of vital statistics than of greater fever prevalence. The Sanitary Commissioner attributes the lower fever death-rate in towns, as compared with rural areas, to the drainage and sanitary requirements of the former being better attended to than those of the latter. Perhaps, also, in towns the diagnosis of disease may be more intelligently effected, and deaths, which are erroneously entered under the heading of fever in rural areas, credited in towns to other diseases. Although the scheme for the sale of quinine in the interior of the province has not as yet achieved much success, the Government considers that the results are encouraging in some districts, and desires that district officers will persevere steadily in their efforts to popularise the use of the drug.

7. *Bowel Complaints* caused about the same number of deaths during the past as during each of the three preceding years. "The study of the seasonal incidence of the disease," writes the Sanitary Commissioner, "is very interesting from an etiological point of view. The disease was most fatal "and probably most prevalent in the rainy season from June to September, less so in the hot and "comparatively dry season from March to May. In January and December (the cold months) there "was a further fall in the death-rate from this cause, whilst in October and November, when the "weather was moist and equable, the disease became least fatal."

8. *Sanitary Works.*—No sanitary works of importance were undertaken during the year. The description given of the sanitary condition of some of the larger towns, shows that their most pressing requirements are a good water-supply and an efficient system of drainage; but these are costly requirements, and the practical difficulty in the way of providing them is the want of funds. Mandalay, the largest city according to population, in the province, is still, as regards sanitation, in a very primitive condition. The description given of it on page xxxv. of the Appendix shows that it needs a good water-supply, drainage, and a civilized conservancy system. The last is perhaps the most urgent want, and is now engaging the attention of the authorities. Of Rangoon, the second largest town according to recorded population, the Sanitary Commissioner writes:—"Nothing practical was done during the year to improve or extend the municipal water-supply." Some 65,000 to 70,000 of the inhabitants have still to depend for their water needs on wells and tanks, the majority of which, from their situation and surroundings, are dangerously liable to contamination. In the Appendices full instructions are given for the preparation of their Annual Sanitary Reports by District Medical Officers and Health Officers, as well as a list of the points which should be noted in the Permanent Sanitary Record, which it has been decided to introduce. As guides to those concerned, the instructions and list will doubtless be useful.

9. Briefly, a portion of Upper Burma was overtaken by famine in consequence of crop failure. Except in a few towns, arrangements are not yet in force for the registration of vital statistics in this part of the province, and, consequently, the severity of the famine cannot be gauged by its effect on fecundity or mortality. The Government has now determined to extend to Upper Burma the system of registration which is proving so successful in Lower Burma, but to confine it to a record of deaths only. Cholera mortality was the highest recorded since 1888. The history of the disease during the year adds nothing of practical value to what is already known regarding it. Small-pox was not more than usually fatal. Outbreaks are attributed in the majority of cases to the operations of inoculators, and, in the port towns of Rangoon and Moulmein, to importation of infection by coolies from India. A new Vaccination Bill is about to be introduced, which, the Government believes, will sufficiently guard against the danger of infection being introduced by immigrant coolies. Vaccination made satisfactory progress, but the number of infants vaccinated is still greatly less than the number available for vaccination. More deaths were recorded as due to fevers than during any previous year, a result doubtless due, in part at least, to improvement in the registration of vital statistics rather than to increased fever prevalence. Steady effort is being made to promote the sale of quinine. No sanitary works of importance were executed during the year. In Burma, as in India, the want of funds is the main obstacle in the way of sanitary progress.

9th June 1899.

No. 6.

MEMORANDUM by the ARMY SANITARY COMMISSION on the REPORT of the SANITARY COMMISSIONER of the CENTRAL PROVINCES for 1897.

The history of the year may be said to be the history of the destructive famine officially declared to have set in towards the end of 1896. The succession of bad harvests which led up to this famine reduced the vital stamina of the people, and weakened their resistance to the diseases which usually accompany and follow famine. The mortality of the year was great, and, but for the relief afforded by the Government, would undoubtedly have been much greater. Out of a population of nine and

a half millions, according to the census of 1891, the number of persons in receipt of relief from the State had risen in the month of May to 691,890. Meteorologically, the year is described as one of high monthly mean temperatures and of a rainfall below the mean of the past 31 years. Under such conditions, whilst the death-rate increased beyond that of any previous year the birth-rate showed a marked decrease. The Sanitary Commissioner estimates the population of the provinces in the middle of the year to have been only 9,372,275, as compared with an estimated population of 9,716,419 in the middle of 1894.

2. *Vital Statistics.*—The birth-rate has steadily decreased from 38·82 per thousand of population in 1894 to 26·83 in the year under review. The decrease accompanied, and may be taken as some measure of, the pressure of the hard times caused by a succession of bad harvests. The normal birth-rate is probably rather above than below 40 per thousand of population, and in the year 1881 the rate recorded was 48·94. The mean of the decennium 1881–90 was 41·56. So constant is the influence of diminished prosperity in reducing the birth-rate, that the Chief Commissioner last year stated his belief that such decrease might be accepted "as almost conclusive evidence of the prevalence of pressure on the labouring population." In one district only during the year did the number of births exceed the number of deaths; and in the exception, Sambalpur, neither famine nor scarcity prevailed. In the provinces as a whole the deaths exceeded the births by 403,849. In some districts the mortality was very great. In Bilaspur the death-rate recorded was 95·54, and in Mandla 98·36. Both districts consist largely of hilly and jungle-covered tracts inhabited by a shy and scattered population. Both suffered severely from famine, and the Government experienced the greatest difficulty in providing the inhabitants with adequate relief. During the year, the number of births reported in the Mandla district was only 5,553, whilst the deaths numbered 33,383. There were thus six deaths to every birth. The destructive effects of the famine, and of the diseases which accompanied and followed it, can better be realised from these figures than from any description. Whilst, however, such havoc was being wrought amongst the people, it is doubtful if the work of registration of births and deaths could have been so efficiently carried on as in ordinary times; and it is more than probable that the figures recorded do not include all the births or all the deaths. In the municipal town of Mandla, with a population of 5,057, registration of vital statistics is compulsory: and during the year 1,208 deaths, equal to a ratio of 238·87 per thousand of population, were recorded. These deaths did not, however, all occur amongst the ordinary inhabitants of the town; the majority of those who died were probably famine-stricken wanderers who had come to Mandla in quest of relief. No fewer than 813 of the deaths are stated to have been due to bowel complaints: in other words, to diseases to which the famine-stricken are specially prone. In times of distress such as those which prevailed in the Central Provinces, although all suffer, the feeblest naturally suffer most. Of children under one year of age, 101,969 died out of a total of 268,732, or a ratio of 400·00 per thousand. The unusual heat which prevailed until the setting-in of the rains in June, contributed to the mortality amongst the people exposed to it on the numerous relief works. With the setting-in of the rains, followed by the reaping of the autumn crop in October, the condition of the population underwent amelioration, although even as late as the end of November there were still 151,446 persons in receipt of relief and the mortality continued in many districts to be very high, fever and bowel complaints carrying off numbers who had become enfeebled by severe and prolonged privation.

3. *General History of Chief Diseases.*—Excepting from small-pox, there was an increase of mortality from all of the other chief diseases. The greater part of the increase, however, was due to fever and bowel complaints. It might have been expected that during a year of acute and wide-spread famine, crimes of violence and deaths resulting from them would have shown a marked increase. But, as a matter of fact, deaths arising from wounding and accident increased only from 3,847 in the preceding year to 4,753 in the year under report. It is not perhaps surprising that deaths from suicide, which during the two previous years of privation had increased from 800 in 1894 to 1,044 in 1895, and to 1,161 in 1896, rose in 1897 to 1,424.

4. *Cholera* accounted for 57,131 deaths, or a ratio of 6·01 per thousand of population. Although during the preceding ten years this number has never been reached, yet over fifty thousand deaths from the disease were recorded in 1889 and again in 1896. Only in 1869 has the cholera death-rate exceeded that of the year under report. The seasonal incidence of the disease did not differ to any marked degree from that ordinarily observed during epidemics in the Central Provinces. The month of greatest fatality was June. From January, during which only 283 deaths were recorded, the disease increased in fatality, until in June it was credited with 21,125 deaths. Then followed a rapid decline in the number to 5,243 in July, to 1,960 in August, and to only 51 in December. The first two and last four months of the year were those of least cholera prevalence. Its increase during the first six months was accompanied by unusual heat and dryness. It was not until the 22nd of June, according to the reports of the Commissioner of Settlement and Agriculture, that monsoon conditions were established. The subsequent months were marked by a rapid subsidence of the epidemic. Large collections of people on relief works, many of them in reduced health and suffering from derangement of the digestive system due to insufficient and unsuitable food, doubtless favoured cholera outbreaks. The Sanitary Commissioner gives a brief summary of the district reports on cholera. The endeavours made in some districts to account for outbreaks by tracing them to importation of infection are not very successful. An example or two may be given in illustration of this. In the Narsinghpur district "the disease first made its appearance on the 8th February in " the Gorakhpur outpost to the south-east of the district, and is said to have been introduced by a man " who had been to the Chindwara bazaar." In the Khandwa district "the infection is said to have " been brought from Gogaipura on the border of the Berars, where some men from the Gondwana " tract had gone out to cut bamboos." Obviously, it would be unsafe to base conclusions regarding importation of the disease on such evidence. During a year in which cholera was diffused over the length and breadth of the provinces, search for the entrance into districts of first cases to account for the infection of those districts would not be likely to be often successful. Efforts to trace the origin of outbreaks in jails or lunatic asylums, in which the inmates are under close and constant observation, might be expected to afford the best opportunities of

arriving at exact conclusions. But although cholera appeared in seven jails, we find regarding two of those no opinion expressed as to the cause of its appearance; in a third "the medical officer was "not able to find out how these prisoners contracted the disease"; whilst regarding a fourth we read :—"It is stated that a careful investigation showed that the poison was most likely communicated "by the compounder attached to the poor-house dispensary, who attended cholera cases there, and "thereafter gave in the morning the prophylactic dose of cinchonidine sulphas to prisoners in jail." In the remaining three jails, the medical officer of one of them failed to trace the origin of the disease; whilst in the other two, its introduction was believed to be due to the arrival in jail of prisoners from infected localities. In many of the districts the dissemination of the disease is attributed to water; but the Civil Surgeon of Chindwara "is of opinion that the spread of the disease "could not have been due to the water-supply. He thinks it due to personal contact." In every district the disinfection of wells by permanganate of potassium was carried out during the year, and a *résumé* of the reports submitted on this subject is given in an *appendix* to the Sanitary Commissioner's Report. The statements made in these district reports show that, while some Civil Surgeons are satisfied that disinfection is successful in stopping outbreaks of cholera, others give doubtful or unfavourable opinions, and the rest simply state that the treatment of wells by permanganate of potassium was carried out, but add no opinion as to the efficacy of this treatment. The Sanitary Commissioner himself, however, as the result of great experience gives his own views in the following terms :—"It may be here stated that the use of permanganate of potassium, in the "disinfection of wells against cholera infection, has not resulted in any appreciable diminution in "the number of cases in epidemic times. During the late and other epidemics its efficacy in staying "the disease was not more appreciable than by adopting ordinary measures of precaution regarding "pollution and contamination by preventing general, or greatly limiting, access to the general supply. "The application, in fact, of permanganate of potassium to ordinary unprotected water-supplies, does "not, it may be definitely stated, much or materially diminish the risk of cholera infection in "epidemic times." As helping to throw light on the question of cholera mortality amongst the labourers recruited for employment in Assam, which has long engaged the earnest attention of the Government of that province, a remark made regarding the history of the disease in the Bilaspur district is worth quoting :—"The disease prevailed during the whole year. The epidemic of 1896 "did not cease, and sporadic cases kept cropping up among batches of the tea-garden coolie "emigrants."

5. The assembly of large numbers of people on the relief works, which appeared to favour outbreaks of cholera, might have been expected to have favoured the dissemination of small-pox. As a matter of fact, however, the mortality from small-pox was less than half that due to it in the preceding year. The number of deaths fell from 7,747 in 1896, and from a decennial mean of 5,536·8, to 3,641 in the year under report. It may be noted, in passing, that paragraph 93 of the Sanitary Commissioner's Report seems merely to be a repetition of the last line of figures in the table accompanying the preceding paragraph, and might have been omitted. The course of the disease according to monthly incidence was that usual in these provinces. Of the total number of persons who died from it, 888 were infants under one year of age, 1,428 children under 10 years, and the remaining 1,325 persons over 10 years. The number of persons vaccinated by the Provincial Vaccination Department has decreased year by year since 1894–95, when it was 399,879, until during the year under report it was only 306,673. It could scarcely have been otherwise, when it is considered that the number of children born decreased from 368,884 in 1894 to 254,973 in 1897. In addition, it is certain that during a year of so much distress and sickness, a larger proportion of the people than usual, and more especially of young children, must have been unfit to undergo vaccination owing to some form of illness. In view of the exceptional difficulties it had to contend with, it is, the Chief Commissioner thinks, "creditable to the Department that it should be able to "show so good an outturn of work." Of the total number of cases of vaccination, 18·79 per cent. were examined by Civil Surgeons, and of these 92·52 were found to be successful. The percentage of successful cases claimed by the vaccinators themselves was 96·73. In some districts the difference between the percentage of success as ascertained by the Civil Surgeons and that claimed by vaccinators seems to call for inquiry. Of the cases examined by the Civil Surgeon of Chindwara, only 55·88 per cent. were found to be successful, whilst the percentage of success claimed by the vaccinators was 90·39. Similarly in Mandla, whilst the Civil Surgeon found only 69·68 per cent. of the cases examined by him to be successful, the vaccinators recorded 99·20, or nearly cent. per cent. to be successful. In the Chandwara district "vaccination was performed with animal lymph." In the Mandla district "bovine lymph and lanoline paste were both used." Although the great majority of vaccine operations throughout the provinces were performed with animal lymph, humanized lymph as well was used in many of the districts.

6. *Fevers* carried off no fewer than 389,335 of the population. As usual, however, in this number are included many deaths from other diseases, and particularly deaths from acute dysentery and diarrhœa. A careful inquiry has led to the conclusion that the fever was of the ordinary malarial type, and that the suspicions entertained in some quarters that it was contagious were groundless. As in ordinary years, it was most prevalent and fatal in the autumn months, the ratio of mortality due to it having exceeded 5 *per mille* of population in each of the months of August, September, and October, and fallen to 2·77 in December. "It has been a matter of common observation in "former famine periods," writes the Sanitary Commissioner, "that fevers of a fatal type prevailed "during the autumn following; and this is accounted for by the fact that the fall of heavy monsoon "rain after prolonged drought, greatly favours the development of the natural phenomena and "conditions which promote a pernicious type of malarial fever which attacks rich and poor alike, but "especially carries off the debilitated by famine and privation." In 1869 the Chief Commissioner wrote :—"The exceptional mortality of the year began just when the famine ended, and when bad "and insufficient food had produced its full effect." In some districts inquiry showed that a large proportion of the deaths returned as having been caused by fever were really due to other diseases. In the Balaghat district, for example, "about 45 per cent. of the deaths investigated were actually "due to acute diarrhœa and dysentery, but returned as fever."

7. *Dysentery and Diarrhœa* in a year of so great privation were certain to be unusually prevalent and fatal. The death-rate from them was nearly four times greater than the mean of the decennium; and it is certain that, as already stated, many deaths were returned as having been caused by fever which were really due to dysentery or diarrhœa. The months of highest mortality from bowel complaints were likewise the months of highest fever mortality. In some districts the death-rate recorded was excessive. Whilst the provincial rate was only 8·53, that recorded in Murwara was 24·14, and in the Mandla district 23·12 per 1,000 of population.

8. *Sanitary Works.*—A detailed account of these is given in Section IX. of the Report. The most important of them were in connection with improvement of the water-supply. The new waterworks at Warda made good progress and were approaching completion. The supply for Jubbulpore was much improved; whilst a large number of wells in the other districts were cleaned out and repaired. Although sanitary works on a large scale could not be carried out during a year when all the available funds were required for the relief of distress, yet it is evident, from the account given by the Sanitary Commissioner, that many useful improvements of a simple and inexpensive nature were effected throughout the provinces.

9. The Village Sanitation Act (Act XIX of 1889) has been extended to 43 villages in the Central Provinces, but owing to the same causes which retarded sanitary improvement in towns, progress in these villages was necessarily impeded. The whole expenditure under the Act amounted only to Rs. 8,878. 7. 10. It speaks well for the efficiency of the sanitary arrangements at the many fairs held during the year, that in the case of none of them was there any outbreak of epidemic disease. The Sanitary Board met once during the year in each of the four divisions of the Central Provinces, and the minutes of the proceedings are printed as an *appendix* to the Sanitary Report. "The expenditure "on sanitary works during the year was very small. In some districts the work of sanitary "improvement was, on account of the general distress and want of funds, very much curtailed, "and in several districts was brought to a standstill by reason of the famine."

10. Briefly, the year 1897 was the most disastrous on record. Acute famine following a succession of bad harvests pressed severely on the people, and necessitated the giving of assistance on a vast scale by the Government. The numbers in receipt of relief had in the month of May attained a maximum of 691,890. Whilst the birth-rate decreased from a mean of 41·56 per thousand during the decennium 1881–90 to only 26·83 in the year under report, the death-rate rose from a mean annual rate of 33·76 in the five years 1891–95 to 69·34. The deaths exceeded the births by no fewer than 403,849. Cholera, fever, and bowel complaints carried off large numbers of those enfeebled by prolonged privation. Collections of people on the relief works seemed to favour outbreaks of cholera. In the autumn months malarial fevers were excessively destructive. Bowel complaints, due to insufficient and unsuitable food, were the causes of more than the 81,092 deaths with which they are credited. Inquiry in certain districts showed that many deaths due to these scourges of the famine-stricken were entered in the returns under the head of fever. Small-pox was not specially prevalent. Considering the great difficulties the Vaccination Department had to contend with, and the decrease in the birth-rate, the number of persons vaccinated was higher than might have been expected. A considerable amount of useful sanitary work was carried out; but the diversion of funds to the relief of distress, and the employment of all available officers in the management of relief operations, necessarily retarded sanitary progress.

9th June 1899.

No. 7.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Assam for 1897.

In the provincial review of the Sanitary Report, 1897 is described as having been most unhealthy and a season of extraordinary trial. This description is fully borne out by the vital statistics of the year. In a population of just over five millions the number of deaths exceeded the number of births by no fewer than 90,476. In some of the congested divisions of Bengal and the North-Western Provinces such a loss of population might have no very serious effect on their posterity; but in a new province like Assam, which above everything needs more people for its development, it could not fail sensibly to check its progress. Taking the meteorological records available for the three districts of Cachar, Goalpara, and Sibsagar as representing the climatic conditions of the province for the year, it appears that, in the first of these, the temperature was about the average and the rainfall 25·29 inches per cent. below it; in the second, the mean temperature was slightly, and the rainfall considerably, above the average; whilst in the third, the temperature was somewhat, and the rainfall considerably, above the average. In the first two of the three districts named the price of food was much, and in the last slightly, above the average for the five years 1892–96. Doubtless the dearness of food would have an unfavourable effect on the health of the population; but the meteorological features of the season as above described do not differ so materially from those ordinarily prevailing as to afford a sufficient explanation of the unusual unhealthiness of the year. On the contrary, it might have been expected that a decrease of the rainfall in Cachar from 140·91 to 115·62 inches would have been accompanied by a decrease in the prevalence of malarial diseases. So far, however, was this from having been the case, that "the fever death-rate was much more than double, and the "death-rate from bowel complaints was much greater than the average of the previous five years." In the other two districts the rainfall, as already stated, was considerably greater than ordinary, and

yet in the one fever mortality was only slightly greater, whilst in the other it was slightly less than the average. In other parts of India the lessened rainfall of the year, although disastrous to the crops and indirectly to the health of the people by causing scarcity or dearness of food, was yet attended by diminished prevalence of malarial diseases. In Assam, or at least in the districts for which meteorological records are given, diminished rainfall and increase of fever went together; whilst increased rainfall was accompanied by only a slight increase, or even by a decrease of fever. In addition to other influences affecting the health of the province, the Chief Commissioner considers that the disastrous earthquake which occurred in June may have been connected with the epidemic prevalence of cholera, especially during the last three months of the year:—"It appears to the Chief "Commissioner that it may be attributed to the floods (which were the direct result of the earthquake, "owing to the falling-in of the river banks and the raising of river beds), which, when they receded, "left, as excessive floods will do, the surface of the country saturated with malaria and the germs of "disease."

2. *Vital Statistics.*—The birth-rate recorded for the year was 32·59 per 1,000 of population, as compared with 33·69 for the preceding year, and with 31·39, the average for the five years 1892–96. This rate exceeds that recorded in the North-Western Provinces, Burma, Madras, and the Central Provinces. Yet, there can be no doubt that, owing to defective registration, it is understated. In the district of Goalpara, as the result of the great interest taken in registration by the District Superintendent of Police, a birth-rate of 45·12 was recorded; whilst in the rest of the Assam Valley, excluding Goalpara, the rate was only 27·05. In his review of the Sanitary Report, the Chief Commissioner observes:—"In the districts of Assam proper there has been no improvement in the registration by "unpaid *gaonburas*, and the checking of village registers by the police and by inspectors of vaccination "appears to have been generally perfunctory." The results of the checking of village registers are given at pages 12 and 13 of the Sanitary Commissioner's Report, and fully confirm the belief that the checking was carried out in a perfunctory manner. In the Sylhet, Darrang, Sibsagar, Lakhimpur, and Khasi and Jaintia Hills districts, not a single omission of a birth or a death was detected by the inspectors of vaccination, "although it is known that registration of vital occurrences is very "imperfectly carried out in all the districts."

3. The *death-rate* of the preceding year was described as the highest on record. It was then, however, only 36·33 per 1,000 of population. The death-rate for the year under review was 50·61. No doubt both years, as compared with preceding years, are to some extent indebted to improved registration for the increase; but, as compared with each other, the influence of improved registration on the records of the second of two consecutive years would probably be but slight. Such a conclusion would seem to receive support from the fact that, whilst the death-rate of 1897 was so greatly higher than the death-rate of 1896, the birth-rate of the former shows a decrease as compared with that of the latter. High although the death-rate of 50·61 is, it is certainly below the actual rate. A reference to page 12 of the Report leaves no room for doubt on this point. In the Cachar district 9,548 deaths were checked, with the result that 529 unreported deaths were discovered. So also in Sylhet and Goalpara districts, 2,277 deaths were discovered to have escaped registration in 3,928 villages in the former, and 725 in 706 villages in the latter district. Excepting in the Central Provinces, in which severe famine prevailed, and in which the death-rate reached 69·34 per thousand of population, in no other province of India was the rate for the year so high as in Assam.

4. *General History of the Chief Diseases.*—The number of deaths recorded under the head of each cause, except small-pox, shows an increase over the number for 1896. In the case of *cholera* the number is nearly double. During the preceding year cholera accounted for 17,042 deaths; and in the year under report for 33,240. As usual, the incidence of the disease varied greatly in different districts. In the two adjoining districts of Goalpara and Kamrup in the Brahmaputra Valley the cholera death-rate was excessive, reaching 10·35 in the former and 17·46 *per mille* of population in the latter. In the districts of Nowgong and Sylhet, the former in the Brahmaputra and the latter in the Surma Valley, the rates were respectively only 2·03 and 3·36. In the chief towns of the province the mortality varied within still wider limits. In Dubri the cholera death-rate was 58·86, and in Tezpur 62·08 per thousand of the population of these towns; whilst in Nowgong it was only 0·62, and in Dibrugarh 0·81. The only two towns in the province in which waterworks have yet been constructed show respectively death-rates of 9·42 and 1·04. The Sanitary Commissioner accounts for the enormous mortality in the towns of Tezpur, Dubri, and Silchar as follows:—"A large number of "cases of cholera occurred amongst coolies going up the Brahmaputra and Surma rivers in steamers "during the first quarter of the year, and 470 cholera deaths occurred at these places amongst coolies "who were landed suffering from the disease, 21 at Silchar, 216 at Dubri, and 233 at Tezpur. "Excluding these 470 deaths, the cholera death-rate in *sadar* towns was 5·20 per 1,000, somewhat "less than the rate in the province as a whole." The Surma and Brahmaputra Valleys are, the Sanitary Commissioner affirms, the endemic home of cholera; and deaths from the disease were, in accordance with ordinary experience, registered in every district during every month of the year. He thinks the probability is that the disease is usually conveyed through the water-supply. "It is "certainly the case that in these two valleys the water-supply is extremely liable to contamination." The Civil Surgeon of Kamrup, the district which shows the highest death-rate, gives it as his opinion that the excessive prevalence of this disease in his district was one of the results of the earthquake. It is shown, however, by the Sanitary Commissioner that cholera was very prevalent in Kamrup in May, the month preceding that in which the earthquake took place; and that during June there was not only no increase but a "sudden drop" in the prevalence of the disease. He admits, however, that "several local outbreaks, notably the one at Barpeta, were probably increased by the pollution "of the water-supply produced by the disturbances caused by the earthquake." In dealing with the cholera epidemic of the year, the Chief Commissioner considers that the Sanitary Report does not furnish adequate information regarding the epidemic which occurred among immigrant coolies on the river steamers during the first three months of the year. That the importation of the disease by these coolies had a very decided effect on the death-rate of the towns at which they were landed has already been shown. In the 8th paragraph of the review by the Chief Commissioner of the Sanitary

Report, the question of the introduction of cholera by the immigrant tea-garden coolies is thoroughly dealt with. If the Sanitary Commissioner is correct in concluding that the disease is endemic in Assam, its introduction by immigrant coolies would not be needful to account for the lighting up of epidemic outbreaks; but the importation of an unprecedented number of coolies, many of them sickly and unfit to undertake the journey from their homes in the famine-stricken districts in which they were recruited, must have had no little effect in disseminating cholera along the lines of their conveyance through the province. The figures given show that amongst these immigration coolies 371 died of cholera on the river steamers and 750 at the depôts after they landed. This mortality need cause no surprise when it is known that "it is the practice both at Goalundo and Jatrapur to "ship coolies with all despatch, and no regard has hitherto been paid to the all-important matter of "allowing only those to embark who are not tainted by association with those who are sick or have "died from cholera." It is, however, satisfactory to learn that the Assam Government has adopted measures which are calculated to prevent a recurrence of the terrible cholera mortality amongst the coolie immigrants which has been so deplorable a feature in the sanitary history of the year.

5. The mortality from *small-pox* was slightly less than it was in the previous year, but nearly double the average of the five-year period 1891–95. The death-rate from this disease was 1·08 in the year under review, and 1·09 in 1896; whilst the average for the previous five years did not exceed 0·57. In the Sibsagar district small-pox prevailed in severe epidemic form, and was productive of a death-rate of 5·10 per thousand of population. A reference to the diagram in the Annual Vaccination Report for the year 1897–98 shows that, contrary to what might have been expected, the districts with the largest proportion of their population protected by vaccination suffered most during the last seven years. During 1897 small-pox deaths were fewest in Cachar, the district which, with one exception, is least protected by vaccination. The Sanitary Commissioner's explanation of the paradox is probably the correct one. In all districts, even in those in which vaccination is most complete, a considerable proportion of the inhabitants annually escape vaccination. In the absence of small-pox, this unprotected residuum goes on accumulating year by year until small-pox contagion is somehow introduced, when an epidemic follows, of a severity proportionate to the length of time the unprotected residuum has been accumulating. Districts with difficult communications and infrequent intercourse with outside might be expected to escape small-pox infection for more prolonged periods than other districts with greater facilities and freedom of communication. In the former, the unprotected residuum having had a longer time to accumulate, an outbreak of small-pox when it did occur, even in the event of the district showing a higher proportion of population annually vaccinated, might nevertheless be more severe than in the latter. Vaccination made satisfactory progress during 1897–98. There were 2,074 more primary and 3,159 more re-vaccinations than during the preceding year. The recorded percentage of successful cases in primary vaccination was, according to Statement No. I., 98·84, and in re-vaccination 92·05. Both percentages are high, but especially the percentage in re-vaccination. It would be useful to learn what was regarded as "successful" re-vaccination. Some vaccinators are only too ready to record any operation which is followed by the least visible signs of local irritation as entitling it to be recorded in their returns as "successful." No fewer than 150,005 cases of vaccination out of a total of 272,760, excluding 11,154 vaccinations by tea-garden agencies, were seen by inspectors of vaccination, and of these a percentage of 98·14 were found to have been successful. If, however, the quality of the work of these officials may be gauged by its quality in the examination of birth and death registers, it cannot be accepted with complete confidence. We have already seen that in several districts in which registration of vital statistics is known to be very imperfect, the inspectors of vaccination, as the result of their investigations, "found that not a single "birth or death had been omitted" from the registers. When we read that 3,277 arm-to-arm vaccinations were performed and that every one of them were successful, and see in the return on page 4 of the Vaccination Report that cent. per cent. of the cases inspected in the Cachar and Kamrup districts, and 99·76 per cent. out of 24,854 inspected in Goalpara, were found to have been successful, we think, in the words of the Chief Commissioner, there is "need for closer scrutiny of vaccination "results on the part of Civil Surgeons." A satisfactory feature of the season's work is the increase in the number of vaccinations of children under one year of age; this increase was from 44,472 in the previous season to 55,574 in the season under review.

6. The mortality from *fevers* during the past year was the greatest hitherto recorded in Assam. The total number of deaths, including those from *kála-azár*, was 144,307, as compared with 101,347 in 1896, and an average of only 84,774 in the five years 1891–95. In all of the districts, except three, the fever death-rate exceeded 30 *per mille* of population, and in one district was 41·77. The death-rate in Assam from fever alone was higher than the recorded death-rate from all causes in either Madras or Burma. After completion of his investigation into the nature of *kála-azár*, Dr. Leonard Rogers has submitted a report which conclusively shows that a previous investigator, Dr. Giles, was mistaken in regarding *kála-azár* and *anchylostomiasis* as one and the same disease. Dr. Rogers considers *kála-azár* to be an intense form of malarial fever closely resembling, if not absolutely identical with, the so-called "Burdwan Fever," which, during the sixties and early seventies, ravaged the Burdwan Division of Bengal. Subsequently to its abatement in Burdwan in 1874, this "Burdwan "Fever" spread to other districts; and Dr. Rogers shows grounds for believing that it crossed the Brahmaputra from the Rungpore district into Assam. From the accounts given of it by medical officers it seems to have differed in no essential feature from the Assam *kála-azár*. It was acknowledged to be malarial in its nature and to be communicable or contagious. Dr. Rogers is convinced that in these respects the "Burdwan Fever" and the *kála-azár* of Assam are identical. He shows that in its early stage it is impossible to differentiate *kála-azár* from ordinary malarial fever. Although the returns show the deaths from these two forms of fever separately, it is certain that many must be recorded as due to *kála-azár* which should have been recorded under the head of ordinary malarial fever, and *vice versâ*. *Kála-azár* is shown to have been slowly but surely spreading up the Assam Valley for the last 20 years, and Dr. Rogers, taking into account its nature and past history, sees no reason for hope that it will spontaneously subside until it reaches the hills that form the easternmost boundary of the valley. Whether the measures proposed by him with a view to arresting its progress will prove successful remains to be seen. The difficulty will be to carry out

these measures in their integrity. The Chief Commissioner considers that the scheme for the sale of quinine is making satisfactory progress. During the year 2,181 packets, each containing 102 five-grain doses, were sold, as compared with only 1,059 packets in 1896.

7. *Sanitary Works.*—Regarding urban sanitation the Chief Commissioner writes :—" No important " sanitary improvements could be carried out, as most municipalities were compelled to devote all " their available resources to the repair of damages caused by the earthquake, and the incomes of " many were curtailed by the remission of taxation which that calamity necessitated." Regarding the proposal to introduce into Assam a Village Sanitation Regulation on the lines of the North-Western Provinces Sanitary Act II of 1895, the Chief Commissioner says that, so far as he can judge, " the only practical result of the enforcement of such a regulation would be the harassment of remote " villages inhabited by an ignorant peasantry, and he is not prepared to take any steps for furthering " its enactment."

8. Briefly told, the year 1897 in Assam was, from a health point of view, the most disastrous on record. Accompanying a diminished birth-rate, the death-rate was unprecedently high. The mortality from all the chief causes of death, excepting small-pox, was excessive. Cholera caused nearly twice as many deaths as in the preceding year. The question of its prevalence amongst the coolies imported from other provinces into Assam has been thoroughly dealt with by the Government of the province, and measures adopted which, it is believed, will have the effect of reducing in future the mortality from this disease. Small-pox mortality was nearly the same as during the preceding year. Vaccination makes satisfactory progress, especially as regards the number of infants vaccinated. Dr. Rogers records the results of his investigation into the nature of *kála-azár* in a lucid and interesting report. He is satisfied that this disease is an intense and contagious form of malarial fever, closely allied to, if not identical with, the destructive " Burdwan Fever " of the sixties and seventies. Whether the measures he proposes with a view to stay its progress will prove successful remains to be seen. The progress of sanitary works has been temporarily arrested by the damage and loss arising from the destructive earthquake of June. Wisely, it appears to us, the Chief Commissioner declines at present to further the introduction of a Village Sanitary Regulation on the lines of the North-Western Provinces Sanitary Act II of 1895, as being likely to lead to the harassment of the ignorant villagers without compensating benefit to health.

9th June 1899.

No. 8.

Memorandum by the Army Sanitary Commission on the Rajputana Sanitary, Vaccination, Dispensary, and Jail Report for 1897.

Approximately correct returns are still available only for the tract of country known as Ajmere-Merwara, or the Ajmere Division. The population of this division, numbering according to last census 542,358, is less than half the population of many a single district of an Indian Province. The population of the 21 Native States dealt with in the Report is not known for certain, but is " computed " to be 11,688,720. Until reliable statistics are available for this vast country and numerous population, useful deductions regarding the incidence of disease and the influence of sanitary measures on the public health cannot be drawn. In 17 of the States some attempt is made to register births and deaths, but hitherto with only indifferent success. This is evident when it is seen that, for these as a whole, the average birth-rate recorded was only 13·90 and the average death-rate only 15·12 per thousand of population. In one of the States a ratio of 2·81 births and of 2·79 deaths is recorded. Obviously, it would serve no useful purpose to treat such figures seriously.

2. In spite of the high prices which prevailed in Ajmere-Merwara, the year under report was not an unhealthy one. The recorded rainfall, though less than that of 1896, was above the average of the preceding six years. Whilst the birth-rate increased from 32·77 in the previous year to 33·69, the death-rate at the same time fell from 28·25 to 24·68 per thousand of population. These figures appear to show that even in the Ajmere Division, with its small population of rather over half a million, there is still room for improvement in the registration of vital statistics. In a year of high prices and immediately following one of scarcity, a death-rate of 24·68 *per mille* of population probably represents but a part of the whole mortality. *Fevers* were credited with 81·20 per cent. of the total number of deaths from all causes. *Cholera* and *small-pox* between them caused only 177 deaths. The mortality from small-pox was little more than a twenty-fourth of what occurred in the preceding year. " More efficient vaccination is being done throughout Ajmere-Merwara," writes the Administrative Medical Officer, " and the supervision has been improved, so it is hoped the mortality " from small-pox will continue to be much lower than it has hitherto been in this Division."

3. The number of primary vaccinations during the year 1897–98 increased from 15,764 to 16,272 successful cases ; and the percentage of success from 96·82 to 98·74. On the other hand, successful re-vaccination cases decreased from 242 to 46. In the Native States there was a large increase in the number both of primary and re-vaccination cases. As in previous years, the recorded percentage of successful cases in some of the Native States is surprising. In six of these States upwards of 99 per cent. of the primary cases of re-vaccination are recorded to have been successful, and in the State of Ulwar the percentage was 99·90. Verification of the returns by Superintendents and Native Superintendents support these remarkable records. The Assistant Superintendent in the City of Jeypore tested 1,224 cases without discovering a single failure amongst them. It is not often that in

provinces under British Administration such ratios of success are recorded; and when they do appear, inquiry generally leads to the conclusion that they are obtained by the exclusion from their registers by the vaccinators of their unsuccessful operations. In his last Annual Report the Administrative Medical Officer directed the attention of Residency and Agency Surgeons "to the "necessity for the more thorough supervision of vaccination," and repeats his injunctions in his report for this year. If a recurrence of the small-pox epidemic, which carried off 3,821 persons, equal to 7·03 per thousand of the population, during the preceding year in the Ajmere Division, is to be avoided, further efforts will have to be made to protect the infant population. Of the 18,271 children born during the calendar year, 2,025 are stated to have died, leaving available for vaccination 16,246. Of these latter, 10,996 were successfully vaccinated; whilst 5,250 remained unprotected. In other words, nearly one of every three children under one year of age available for vaccination remained unvaccinated.

4. During the previous year 16 deaths from *plague*, or suspected plague, were reported from Rajputana. All of these were imported cases. It was not until November of the year under report that a case occurred amongst the indigenous population. In that year "a wealthy Seth found his "way into the village of Tewri in Sirohi State and died there of plague; his funeral ceremony was "well attended, and it was very soon followed by an outbreak of indigenous plague in this and three "other villages adjacent." The mode of introduction of the disease is suggestive of one of the means by which the resistance offered to the admission of infected persons into a district is overcome in India. A poor man from an infected place would probably have been promptly stopped; but the wealthy Seth "successfully evaded detection." The villages in which the disease appeared were evacuated and disinfected, with the result that "the outbreak seemed to stop after this." Unfortunately, the coldness of the weather seems to have driven the people back to their villages before the houses had become safe for re-occupation, and further cases occurred as a consequence. In the Himalayas, when houses in a village are infected with plague, it is usual to burn them down. This drastic treatment effectually puts an end to the risk which might arise from premature re-occupation of infected houses. "The disease was of the pneumonic type and very rapidly fatal at first, but "afterwards glandular swellings were common and some recoveries took place." The Administrative Medical Officer believes that there is nothing more destructive to the plague germ than the heat and light of the sun and free ventilation. This seems to be the experience of others who have been engaged in dealing with plague. Surgeon-Captain Grant's experience on this point should be recorded. He says:—"At first it was the custom to disinfect with perchloride of mercury solution "the clothes and bedding of contacts removed to the segregation camp. A few cases (of course in "the incubation stage at the time of the disinfection) having appeared shortly after the operation, so "much objection was raised, that as the discontent threatened to become universal it had to be given "up for a time. Free exposure of clothes, &c., to the sun's rays had to be trusted to, and this seemed "to answer the purpose equally well." Although the outbreak was alarming, it cannot be said to have been very destructive to life. "In all, there were during the course of the epidemic 166 "indigenous cases and 143 deaths, of which the larger proportion occurred among members of the "baniya caste."

5. The figures given of the numbers of indoor and outdoor patients relieved in the hospitals and dispensaries bear testimony to the popularity and usefulness of those institutions. Of both classes of patients nearly a million were treated. The combined number of surgical operations performed in Ajmere-Merwara and the Native States was 62,004. By far the greater number of patients were treated for diseases of malarial origin. The endeavour to bring quinine within reach of the people remote from hospitals and dispensaries by arranging for its sale at post offices, continues to be attended with considerable success. The number of doses of the drug sold increased from 36,618 in the preceding year to 46,920 in the year under report. It is noted that leprosy, contrary to the fears entertained by some, would seem to be decreasing in Rajputana. "There were 650 cases of leprosy "treated during the year as against 842 in the previous year, a decrease that is the more satisfactory "in view of the increased attendance at dispensaries and hospitals."

6. The health of the Ajmere jail was good. The death-rate therein fell from 13·26 *per mille* of its population in the previous year to 6·84 in the year under report. In the Native State's jails as a whole, also, the death-rate decreased from a ratio per thousand of their inmates of 28·17 to 23·58; but in some of them the mortality was excessive. In previous memoranda we have commented on the unhealthiness of the jail at Banswara. Last year the death-rate in this jail was as high as 131·60 per thousand of strength: in the year under report it has further increased to 174·41. Such figures speak for themselves. In one other jail, that of Dholpore, the prisoners have been more than decimated, and in a third the death-rate was 88·17 per thousand of strength. Regarding jail management of the Rajputana States generally, it is stated that steady progress is being made, and that most of the jails are in good order; but "a few of the old jails are, however, still very defective in drainage, "construction, and management, and in some States there is still much overcrowding of prisoners, "and these defects require early remedy." Consignment to a jail such as that of Banswara means more than imprisonment. The death-rate amongst the free population of the State is recorded to be 18·10 per thousand, and in the jail it is 174·41; so that, in addition to imprisonment the risk to life which a convict undergoes is increased ninefold.

7. It is proposed to appoint an Assistant Surgeon as Health Officer of Ajmere-Merwara. In superintending the collection of vital statistics, vaccination, and sanitation throughout the two districts, he could no doubt be very usefully employed. As regards sanitation in the Native States, the first requirements are the correct enumeration of the population, and the institution of an effective system of registration of births and deaths. Until the population of a State is known, and a record kept of the number of births and deaths occurring in it, neither its sanitary needs nor the effects of sanitary improvements carried out in it can be ascertained with an approach to certainty. "Endeavours "are being made to have special registration departments formed," the Agent to the Governor-General writes. It is to be hoped that these endeavours may be persisted in until they are successful.

8. Briefly, the year, in spite of high prices of food grains, was not unhealthy. Whilst the birth-rate increased, the death-rate diminished in the Ajmere Division—the comparatively small portion of Rajputana for which reliable vital statistics are available. This division has a population of only somewhat over half a million; whilst the States, for which reliable vital statistics are not yet available, have a population of upwards of eleven millions. Cholera was in abeyance in Ajmere-Merwara, accounting for only 18 deaths. Following the severe small-pox epidemic of the preceding year, the deaths from that disease numbered only 158. There was some increase in the numbers vaccinated in the Ajmere Division; but the returns show that about one of every three children under one year of age available for vaccination remains unvaccinated. The accumulation of this unprotected residuum renders the recurrence of another epidemic of small-pox at no distant date more than a probability. As in former years, the percentage of successful cases of vaccination obtained in some of the Native States was remarkable. Humanized vaccine lymph is still in general use in Rajputana; and if the recorded percentage of successful cases is to be accepted, no substitute for it has yet been found which excels it in efficiency. Plague succeeded in effecting a lodgment amongst the indigenous population of Rajputana during November; but the mortality caused thereby was not very great. The evacuation of the infected villages, here as elsewhere, proved the most effectual measure for staying the progress of the disease. The number, popularity, and usefulness of the hospitals and dispensaries continue to increase from year to year. Jail improvement is receiving attention; but there are still some old and defective prisons in which the mortality is lamentable. In the Banswara jail the death-rate in 1896 was 131·60; and in the year under report rose to 174·41 per thousand of its inmates. It is to be hoped that in the near future it may be found possible to obtain a correct census of the population of the several States of Rajputana, and to introduce into them an efficient system of registration of births and deaths. The record of vital statistics is a preliminary and essential step if sanitation is to be conducted on intelligent principles.

10th August 1899.

No. 9.

Memorandum by the Army Sanitary Commission on the Medical and Sanitary Report of Coorg for 1897.

The year was an unusually unhealthy one. The mortality from the chief diseases, excluding small-pox, was the highest hitherto recorded. Fever mortality was more than twice as great as in the preceding year, and exactly twice as great as the average of the five-year period 1892–96. Bowel complaints were also unusually fatal. The rainfall recorded was 134·04 inches, as compared with 157·6 in the previous year, and with a quinquennial average of 119·19 for 1892–96. The mean temperature of the year exceeded that of 1896 by only two decimals, and was less than that of 1894. Accompanying these climatic conditions, the price of the staple food of the people was higher than that which prevailed in the preceding year, and than the average for the five years 1892–96. Although the price of rice was exactly the same as the average price for the quinquennial period 1892–96, and only a fraction higher than in 1896, the rise in the price of *ragi*, the staple food of the poor, was serious: the average for the quinquennium 1892–96 was 26·7 seers of *ragi* per rupee, and in the year under report only 19·5 seers. "The high price of food grains began to be felt during the "monsoon months, a time when the people required good nourishment." To this the Civil Surgeon adds:—"Although there was no famine in the province itself, the effects of it in other places "influenced the high mortality of Coorg by the influx of people coming to seek employment." But, beyond such influences as high prices and meteorological conditions, there must have been an additional something to account for the prevalence of fatality of the fever, which caused 41·50 of a total death-rate of 50·02 per thousand of population. There is no evidence to show that this was other than an intense form of the ordinary malarial fever annually prevailing. It "attacked both "rich and poor, and at one time threatened to cause serious hindrance to Government work, owing "to the number of officials who were down with it. All alike, Europeans and Natives, suffered from "it, but its symptoms were those of a malarial fever and not of famine fever." Much remains to be discovered regarding the causes which give rise to those wide-spread and fatal epidemics of malarial fever which periodically visit the different provinces of India. In the present case, neither the climatic features of the year nor the high prices of food were of so exceptional a character as, of themselves, to afford a sufficient explanation.

2. *Vital Statistics.*—Last year there was a slight excess of births over deaths; but during the year under report the number of births was less than half the number of deaths. Whilst the births decreased from 4,606 in the previous year to 3,503 in the year under report, the deaths at the same time increased from 4,574 to 8,658. The unhealthiness of the year no doubt to some extent affected the birth-rate, although this would chiefly be influenced by the health conditions of the previous year. Registration is still acknowledged to be defective, but it is probably improving rather than retrograding, and would not, therefore, account for a falling-off in the number of children born in the year 1897 as compared with the number born in 1896. The recorded ratio of births per thousand of population was 20·24. It has been more than once explained that, apart from defective registration and unhealthy seasons, the proportion of the sexes constituting the population must necessarily exercise a marked influence on the vital statistics of the province. Of a population of 173,055 in Coorg, more than 50,000 are immigrant coolies who come annually, mostly without their wives and families, to work on coffee estates. These coolies, constituting more than a fourth of the population, necessarily lower the birth-rate calculated on the census figures, and, as they succumb in large

numbers to the climate of Coorg, they at the same time raise the death-rate. In spite of the efforts made by the Administration to protect these immigrants from the injurious effects of the climate, they continue still abnormally to swell the death-rate of the province. Indeed, it has been definitely shown that the abnormal features of the vital statistics of Coorg are mainly due to the presence in its population of the immigrant coolie element. At the taking of the census of 1891 the Superintendent of Census operations showed that, although there was a decrease in the total population of the province since the taking of the previous census, this decrease was confined entirely to the immigrant coolie element; and that there was not only no decrease, but an increase of 16·12 per cent. of the indigenous portion of the population since 1881. During this intercensus period the immigrant population showed a decrease of 29·28 per cent. That defective registration, however, plays its part in the production of some of the peculiarities in the ratios of births and deaths seems more than probable. An examination of the figures in Annual Form I. shows remarkable and unexplained differences, especially in the birth-rates of the five districts composing the province. In the Mercara Taluk the ratio is only 16·59, and in the Yedenalknad Taluk 15·36 *per mille* of population; whilst in the Nanjarajpatna Taluk it is 26·12 *per mille*. It might be useful if, as in Burma and other provinces, the Civil Surgeon of Coorg submitted to the Commission a quarterly review of the returns of births and deaths of the several registration circles. In this he might invite attention to those circles in which the figures led him to suspect defective registration, and ask for an inquiry into the cause of the deviation of the figures from normal.

3. *Chief Diseases.*—Regarding *cholera* and *small-pox* no special remarks seem to be called for The former of these diseases is credited with 106, and the latter with 59 deaths. Both were more fatal than during the previous year; but in the case of small-pox the ratio of deaths per thousand of population was greatly less than the mean for the previous five years. Taking into account the unhealthiness of the year, vaccination made satisfactory progress. There were 10,977 people vaccinated, including dispensary vaccination and re-vaccination. There would have been even a larger number of vaccinations performed had not so many been rendered unfit to be operated on owing to weakness following the fever, which caused so much sickness and so high a rate of mortality among children. Of infants under one year of age only 907 were successfully vaccinated, as compared with 1,289; and of children under six years, 4,059, as compared with 4,113 in the preceding year. Both in primary vaccination and in re-vaccination the percentage of successful cases was higher than in the previous year, having been in the case of primary vaccination 95·21, and of re-vaccination 85·04, according to paragraph 3 of the Vaccination Report. Calf lymph only was used throughout. Turning to page 14 of the Appendix, Statement No. I. gives the percentage of successful cases of re-vaccination as 89·25, excluding dispensary vaccination cases. This is suspiciously high and would seem to suggest the need for inquiry. Statement No. V., page 17 of the Appendix, shows that the Civil Surgeon tested 170 cases of vaccination and found a percentage of only 90·00 successful; whilst Native Superintendents, or other inspecting officers, tested 3,505 cases and found a percentage of 98·94 successful, as against a percentage of 93·82 recorded by the vaccinators. It is not clear, however, whether in this statement the percentage is calculated on primary cases only, or on mixed primary and re-vaccination cases. Probably the latter of these suppositions is the correct one, as the percentage of success in primary cases shown in Statement No. I. is 95·80, and this is presumably the percentage calculated on the returns submitted by the vaccinators. "With regard "to the total population, 59·51 *per mille* were protected by vaccination, as compared with 56·72 in "the previous year, showing an increase of 2·79 *per mille*." Seeing that the recorded birth-rate was only 20·4, a vaccinated ratio of 59·51 per thousand would, taken by itself, seem to indicate that the population of Coorg was exceptionally well protected against small-pox. The practical test afforded by small-pox mortality does not, however, support such a conclusion. The average small-pox death rate for the fifteen years, beginning with 1882–83 and ending with the year under report, was 1·17 per thousand of population, and in 1892–93 the rate was as high as 5·27.

4. *Fever* was excessively prevalent and fatal. Of the total number of 8,658 deaths, no fewer than 7,182 were due to this cause alone; whilst 538 more were due to dysentery and diarrhœa. It would be useful if a return could be prepared giving the number of deaths amongst the immigrant coolies separately from the deaths amongst the indigenous population of the province. It is gathered from the account given of these coolies that they succumb in great numbers to the climate of Coorg. There are also some figures available which tend to confirm this conclusion. "In Mercara town there were 301 deaths; of these, 166 occurred in the hospital, 81 of which "were known to have occurred among coolies from Mysore, Malabar, South Canara, &c." Also in Virajendrapet "out of 519 deaths, 280 occurred in hospital, and of the latter no less than 238 were "known to have been coolies from Malabar, &c., on their way to or from coffee estates." From such statements it would appear that the high rate of mortality for the province was largely due to the greater liability to sickness and death of the 50,000 immigrant coolies annually coming to work on the coffee estates. Consequently, the measures most likely to be effectual in lessening this mortality would be such as would tend to remove the causes of sickness and mortality among these coolies. Already three shelters have been erected on the *ghâts*, and a fourth is being built for the use of the coolies entering and leaving the province. These, the Commissioner states, proved most useful last rains; but the President of the Sanitary Board is doubtless right in concluding that "without food or clothing shelters alone would not be sufficient to check the mortality now "brought to notice." We agree with the Civil Surgeon when he says that "although the shelters "were good so far as they went, they did not go to the root of the evil." He recommended an examination of coolies in the low country as to their fitness to come to Coorg, and that labour contractors should be allowed only to bring up coolies passed as medically fit; he further suggested that both maistries and labour contractors should be held responsible for the health of their coolies. Some such measures will have to be adopted if the lamentable mortality annually occurring amongst this class of labourers is to be checked. Not unnaturally, the Civil Surgeon's proposal was not favourably received by the representative of the planters' interests. The latter feared that a labour law, or a medical examination might interfere with the supply of labour; but when the people of the countries supplying the coolies fully realise the dangers to life and

health which emigrants to Coorg have to encounter, their unwillingness to meet these dangers may come by and by to render them disinclined to go there, and in this way more injuriously affect the labour supply than a medical examination or a Labour Act. Whatever their effect on coolie recruitment, effectual measures will have to be taken with the object of protecting the coolies, as far as may be found practicable, from the influences which have caused in the past, and are still causing, the excessive mortality annually occurring among them. The high death-rate, from dysentery and diarrhœa are suggestive of an insufficient or unsuitable dietary. The healthy condition of the prisoners in jail, during the months when the free population were dying in hundreds of fever and bowel complaints, goes to show that climate alone will not account for the fatality of these diseases. "During the most unhealthy period among the general population of "Mercara, the health of the prisoners was exceptionally good, and there was not a single admission "into hospital from the 20th July to the 30th September." It must be noted, however, that the average strength of the jail population was only 79·32, a number insufficient to form a basis for safe deductions. During the year the sale of quinine is said to have been successful.

5. Of the system of Village Sanitary Inspection Books prescribed by the Government of India, the Chief Commissioner remarks that it seems to have been a failure in Coorg.

6. Briefly, the year was very unhealthy and the mortality excessive. Climatic conditions were not of a specially exceptional character, although the rainfall was above the average for the preceding five-year period. The price of *ragi*, the staple grain used by the poor, rose from an average of 26·7 seers per rupee in the preceding five years, to 19·5 seers in the year under report. This doubtless unfavourably affected the public health. The number of births was less than half the number of deaths. Cholera and small-pox were between them accountable for 165 deaths, a number which looks insignificant by the side of 7,182 caused by fever and 583 by dysentery and diarrhœa. These latter diseases were unusually destructive of life. The 50,000 immigrant coolies annually entering Coorg in quest of employment on the coffee estates, suffered out of all proportion as compared with the indigenous population of the province. Indeed, the sanitary problem in Coorg in most urgent need of solution is how to lessen the mortality among the immigrant coolies, who constitute over a fourth of the entire population of the province. Something has been done to provide them with shelter on their way into and out of the province annually; but this does not reach the root of the evil, and if the lamentable loss of life yearly occurring amongst them is to be checked, measures of a more radical and far-reaching nature will have to be adopted.

9th June 1899.

No. 10.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Madras for 1897.

The first 13 pages of the volume are taken up with the Report of the Sanitary Board for 1897 and its Appendix. Besides scrutinizing the plans and estimates of 185 sanitary works of an estimated value of nearly twelve lakhs of rupees, the Board issued to local bodies carefully worded circulars with instructions to help them in preparing plans and estimates of sanitary works. With type designs already in their possession, and this code of instructions to guide them, local bodies should now be in a position to submit their projects in a form capable of being dealt with by the Board. Hitherto, much trouble and delay have been occasioned owing to the defective state in which plans and estimates have been sent up to the Board. The question of a bacteriologist for the Presidency has been under the Board's consideration. The opinion of the Board is in favour of such an appointment; and it is stated that the Government, having arrived at the conclusion that there was a large scope for a bacteriologist in the Presidency, "advised the Government of India accordingly."

2. Famine, owing to crop failure following deficient and unreasonable rainfall in 1896, continued until October of the year under report. At the time of greatest pressure the area declared to be affected covered upwards of twenty-six thousand square miles, with a population of more than five and a half millions. The year's rainfall was considerably above that of the previous year, as well as that of the ten years ending 1894. The fall during the south-west monsoon was 9·04 inches above, and the fall during the north-east monsoon 6·98 inches below, the average. The prices of food grains were greatly higher than in the previous year, and than the average for the ten years ending 1894. For the whole Presidency the normal price of staple food grains was exceeded by 62·1 per cent.; but as the Sanitary Commissioner observes, average rates for districts give but a rough idea of the extent to which high prices prevailed in certain parts. In one locality he found that *cholum*, or *jawari*, was 251 per cent. above normal, and adds :—"This, as it "happened, was not only the price of the staple grain, but of the only grain available. As giving "some idea, beyond the quoting of these percentages of the range of high prices, I may state that, in "certain months and localities in the Ceded Districts, the price of the staple grain was the same as in "the great famine of 1877 and 1878." The effects of these conditions on the health of the Province as a whole, were not so serious, when judged by their influence on the birth and death rates, as might have been anticipated. It is only by dealing separately with the statistics of the districts which suffered most severely, that the effects of famine on fecundity and mortality are fully brought into view.

3. *Vital Statistics.*—According to the last census, the population of the Presidency numbered 35,641,828, but the population for which vital statistics are recorded numbers only 32,638,243, including Europeans and Eurasians. The birth-rate recorded for the year, excluding Europeans and Eurasians, was 28·7, and the death-rate 25·4 for town and rural circles combined, as compared with 29·9 and 20·6 in the preceding year. Although the rates given are doubtless, owing to defective registration, much understated for both years, and their comparison with the rates for other provinces in which registration is less defective might be misleading, they nevertheless give useful information when compared with each other. The Sanitary Commissioner says: "Registration results are much "vitiated in this Presidency in areas under Zamindars, in consequence of the services of the village "officials responsible for the statistics not being under the full control of the Revenue officers." This explains the first of the measures which the Madras Government last year decided to adopt for the improvement of registration, "by placing the village establishments in the zamindari tracts under "adequate control." A comparison of the results obtained in rural areas with those in municipalities shows that, in the latter, registration is carried out with far greater thoroughness than in the former. Whilst in rural areas a birth-rate of 28·8 per mille is recorded, the rate in municipalities is 34·4; and whilst in rural areas a death-rate of 24·4 is recorded, this in municipalities was 33·3. In paragraph 17 is given a list of the municipal towns in which penalties were inflicted for neglect of registration of vital statistics. From this it appears that in 59 municipalities penalties were inflicted for the omission to register 764 births and 666 deaths. Persistent scrutiny of the registers, and the infliction of a penalty when omission of entries is discovered, rarely fail to bring about improvement. The diagrams inserted between pages 34 and 35 show very clearly the effect of the famine on the birth and death rates. Although the Province generally suffered from high prices, famine was declared to exist in seven districts only. The diagram giving the death-rates shows that, with a single exception, all the registration circles returning the highest rates belonged to famine-stricken districts. The second highest series of death-rates also includes registration circles belonging to all the famine districts except Ganjam; and Ganjam does not contribute a circle to this series, because all of its circles, with a single exception, belong to the group recording the highest rates. The effect of famine in lowering the birth-rate is not so marked as in raising the death-rate. Taking the two famine-stricken districts of the Northern Circars as exhibiting most strikingly the effects of the famine on the vital statistics of their population, it is seen that, whilst in Ganjam the birth-rate only fell from a ratio of 26·6 per 1,000 in the preceding year to 23·9 in the year under report, its death-rate rose from 20·6 in the former year to 50·1 in the latter; and that whilst in Vizianagram the birth-rate fell from 31·7 to 28·3, the death-rate at the same time rose from 18·5 to 31·6. These figures demonstrate with sufficient clearness the influence of famine on a population, by checking fecundity and increasing mortality. An additional effect of famine is the stimulus it gives to emigration. Dr. King writes: "There was a net decrease of the "population by 92,118, on account of emigration from the ports of the Presidency. Of the total "number of 275,109 emigrants, 43,518 departed from the ports of Ganjam, Vizianagram, and Godavari. 'From these ports the emigration amounted to 1,996 above that for the previous year." But for the compensating effect of the unusual dryness, following the early cessation of the rains in the preceding year, in diminishing the prevalence and fatality of diseases of a malarious nature, there can be little doubt that the mortality consequent on the stress of famine and high prices would have been much greater. The death-rates recorded for the province in all of the months up to June, except January, were low, not reaching to 2 per mille of population.

4. *Chief Diseases.*—The deaths from *cholera* reached the enormous total of 143,445 against 47,847 in the previous year, or 4·4 against 1·5 per mille of population. This was for the Province as a whole; but some of the districts taken by themselves suffered far more severely. For example, Ganjam records no fewer than 15,533 deaths from this cause, or a ratio of 12·54 per thousand of its population. The disease prevailed in the Province throughout the entire year, the first death having been reported on the 1st of January and the last on the 31st of December. Town circles suffered more severely than rural circles, the ratio of cholera deaths in the former having been 5·0 as compared with 4·3 in the latter. In some of the municipalities the death-rate was excessive. In Cannanore it was 28·5, in Parlakimedi 23·6, and in Calicut 23·1 per thousand of their populations. Referring to Statement No. XI. of the Appendix, we find noted against Cannanore that the "*drainage* of old town is "defective. The existing cesspools in old town are rarely cleaned. *Water-supply.*—The wells in the "old town are shallow, and are either unprotected or hardly protected. They are near latrines, drains, "or burial grounds." Against Parlakimedi it is recorded:—"*Drainage.*—Only rough stone drains exist "for carriage of storm water. Sewage water from houses soaks into the ground for most part. One "more sewage cart is required. *Water-supply.*—The tanks are subject to gross pollution, fœcal "matter of all sorts being washed into them. Surroundings of private wells are bad. The wells are "constructed with earthen rings which admit of percolation of spilt water." Against Calicut, we read that of drainage there is no regular system, and that, as regards the water-supply, many of the wells in use need protection against contamination. The sanitary defects described are perhaps not more serious than those existing in the majority of the other municipal towns; but they are of such a nature and gravity that their removal would assuredly help to fortify these towns against the recurrence of cholera epidemics so destructive as those by which they were visited in the year under report. Regarding the disinfection of water-supplies, the Sanitary Commissioner states that this "is "freely practised," by permanganate of potash when the supplies to be dealt with are small, and by lime and alum when the supplies are large. "The red colour produced by the permanganate of "potash, which is specially advised by Mr. Hankin, is occasionally objected to; but, on the whole, "both the people and the medical officers regard its use favourably in most districts."

5. *Small-pox* accounted for 21,678 deaths; but the mortality caused by it was not excessive except in a single district. The district of Ganjam contributed 14,515, or more than two-thirds of the total number of deaths, giving a death-rate of 11·7 per thousand of its population. In no other district did the small-pox death-rate reach 1 per thousand; whilst for the province as a whole, including Ganjam, it was only 0·7. The history of small-pox for the year was therefore practically its history in Ganjam. There is no doubt that when the disease broke out in epidemic form in Ganjam its dispersion was much assisted, during a year of famine, by the wandering from village to village of people in search

of employment, as well as by the filthy habits and customs of the Uriyas described by the District Medical and Sanitary Officer; but all of these causes would not have brought about an epidemic attended with so great a loss of life had the population been previously protected by vaccination; nor will all other measures combined prevent a recurrence of destructive epidemics if vaccination is neglected. Regarding the Malabar district, which so long returned the highest death-rate from small-pox, Dr. King writes:—"The vaccination staff has been considerably increased, and much attention "has been paid to perfecting the working of the department in this district. The result is apparently "a steady diminution of small-pox. Of course this *post hoc propter hoc* argument is open to the "criticism that a large number of the population are really now protected not by vaccination but by "previous attacks of small-pox." Without claiming for vaccination that it will completely extinguish small-pox in districts such as Ganjam and Malabar, it is safe to assume from general experience elsewhere, that their small-pox mortality will diminish directly as the protection of their population by vaccination increases. From the table given in paragraph 8 of the Vaccination Report it would appear that, excluding municipalities, only 18·0 per cent. of the population of Ganjam were protected by vaccination. The calculation is based on a return of 22,550 births, but according to Statement No. II., page 76, of the Sanitary Report the births in the Ganjam district in the calendar year 1897 numbered 29,634. Perhaps the difference may be due to the number of births in the 12 months covered by the Vaccination Report being so much smaller than the number in the 12 months of the calendar year covered by the Sanitary Report. Even when the 1,232 births in the three municipal towns of Ganjam are added to the 22,550 for the district, the total falls short of the total given in the Sanitary Report by 5,852. The numbers vaccinated in the Presidency during 1897–98 exceeded those vaccinated during the preceding year by 24,009. The percentage of successful cases were practically the same in both years. Infant vaccination showed a slight increase; but the fact that only 331,297 children under one year of age were successfully vaccinated out of a grand total of 935,845 children born in 1897, exclusive of Europeans, Eurasians, and still births, shows how much remains to be done before the number of children under one year of age protected by vaccination can come anywhere near to the number born. If the 158,263 deaths of children under one year of age be deducted from the number born, there would remain available for vaccination 777,582. Deducting from the latter the number successfully vaccinated, there would remain 446,285 unprotected. The circumstance that the 12 months of the vaccination year do not entirely coincide with the 12 months of the sanitary year would not ordinarily detract much from the usefulness of a comparison between the numbers born and the numbers vaccinated in the two twelve-month periods. Undoubtedly, a fair proportion of the children under one year of age is protected in the municipal towns of the Presidency. For all of the municipalities combined this proportion averages 84·0 per cent., and compares very favourably with the proportion of 31·8 for districts. The use of human vaccine lymph has been entirely superseded in the Madras Presidency by animal lymph. The latter gave results which varied according to the mode of using it. Applied direct from calf to arm, the percentage of success was 95·5, and preserved in glass 93·9; whilst when preserved with glycerine the percentage was 85·6 and with lanoline only 82·0. In India, at all events, experience, so far, is in favour of fresh lymph whether taken from the calf or the arm. The superiority of lymph from the former source over preserved lymph is well exemplified in Madras.

6. *Fevers* were credited with a ratio of 9·0 deaths per thousand of population, as compared with 8·0 in the preceding year. The extraordinary difference between the mortality attributed to fevers in Madras and the mortality attributed to them in Bengal, Bombay, and the Central Provinces cannot fail to strike any one who examines the returns of the several provinces. Whilst the death-rate from fevers in Madras is represented by a ratio of only 9·0 per mille of population, in Bengal this ratio is 23·62, in Bombay 24·05, and in the Central Provinces 40·98. It is difficult to believe that, as compared with its neighbours, Madras enjoyed the immunity from fever mortality which these figures would indicate. Up to the month of June of the year under report the mortality from fever in Madras was less than during the corresponding period of the previous year. "The comparative "freedom in the early part of the year," writes the Sanitary Commissioner, "must be ascribed to the "diminished soil moisture proving inimical to the propagation of the germ, in consequence of the "failure of the north-west monsoon of the previous year; this was followed by an access of moisture "with the south-west monsoon, in the presence of a population rendered susceptible to malaria owing "to diminished food supply, by a mortality greater than normal under this head."

7. The mortality from *dysentery and diarrhœa* showed, as was only to be expected, a large increase over that of the previous year. The excess was contributed by districts "of which seven were "formally recognized as suffering from famine, whilst in the others undoubtedly a considerable "grade of distress was undergone." The ratio of deaths per mille of population caused by these diseases was 1·2 as compared with 0·7 in the previous year. There are grounds for believing that in all provinces the mortality from these diseases is understated.

8. In spite of the introduction into the Presidency of *Plague* by three persons who had been visiting Poona, the measures taken were effectual in preventing the spread of the disease from these cases as foci. The Sanitary Commissioner is justified in claiming that "whatever may be in store for "this Presidency in the future, it is, humanly speaking, certain that the measures adopted on this "occasion did, at least, defer its fate." The Government of Madras accepted the advice of the Sanitary Commissioner to refrain from the adoption of "any attempt at quarantine by land or sea for "healthy persons or ships."

9. *Sanitary Works.*—"The water-supply works of Kurnool and Conjeeveram which were in "progress in 1896, were completed during the year under review." A number of water-supply and drainage schemes were prepared and submitted to the Sanitary Board. In paragraph 57 of his Report the Sanitary Commissioner writes:—"No advance beyond that reported last year has been "made in respect to sewage farming. Sewage filtration continues to be satisfactorily practised at "Vizagapatam and Vizianagram." The set of recent opinion amongst practical sanitarians is against the disposal of sewage by discharging it into rivers or the sea, and of night-soil and sweepings by burning them. The old principle of restoring to the soil what has been taken from the soil is again

finding favour; and its soundness being demonstrated by the success attending the use in cultivation of the valuable manures now being wasted or destroyed at much cost. It is claimed that these materials can be disposed of with safety to the public health and with profit to towns by utilizing them as manures. India would seem to be well situated for this method of disposing of the waste products of towns; and the check in the progress of sewage-farming mentioned by Dr. King is matter for regret. Neither in Madras nor in any other province has the scheme for maintaining Village Inspection Books, so far, proved much of a success. To paragraph 65 of his Report the Sanitary Commissioner appends a list of 18 districts in which the scheme is being tried; but an examination of the remarks entered against each district leads to the conclusion that, in many cases, little progress has hitherto been made in the record of useful sanitary notes in these books.

10. To sum up, the year was one of famine and high prices. Following the drought of the latter part of 1896, the first months of the year under report were, owing to their unusual dryness, unfavourable to the production of malarial diseases. Under the influence of privation during the latter part of the previous year and the early months of the year under report, the birth-rate fell considerably, the fall being most marked in the districts declared to be famine stricken. The death-rate rose from a ratio of 20·6 in the previous year to a ratio of 25·4 for the province as a whole; but in the districts affected by famine the rise was much greater. In one of the latter the rise was from 20·6 to 50·1 per mille of its population. Yet, there can be no question that, owing to defective registration, a large proportion of the deaths still remains unrecorded. Cholera was terribly fatal, accounting for a ratio of 4·4 deaths per thousand of the provincial population. In the district of Ganjam the ratio was as high as 12·54 and in several towns exceeded 20 per mille. Small-pox caused over twenty thousand deaths, but its ravages were mainly confined to the single district of Ganjam, in which it accounted for 14,515 deaths. Of this district it is recorded that only 18·0 per cent. of the children under one year of age were successfully vaccinated. The numbers vaccinated in the province show a considerable increase as compared with those of the previous year; whilst the percentage of successful cases continues about the same. Animal vaccine lymph alone is used in Madras. When applied direct from calf to arm it gave a percentage of 95·5 successful cases, but when preserved with glycerine only 85·6, and with lanoline only 82·0. Fever was credited with a death-rate of 9·0. This is probably but a part of the actual death-rate from this cause, seeing that in the adjoining province of Bengal the rate was 23·62, of Bombay 24·05, and of the Central Provinces 40·98. Plague obtained entrance into the Presidency, but the measures adopted to prevent its spread proved successful. Several sanitary surveys have been made and water-supply and drainage schemes prepared for submission to the Sanitary Board. The water-supply works of Kurnool and Conjeeveram were completed during the year.

9th June 1899.

No. 11.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bombay for 1897.

Famine and plague combined to make the year unhealthy. The former was a continuation of the famine officially declared to exist in the last months of the preceding year, and did not relax its severity until towards the end of nine months of the year under report. Climatically considered, the season of 1897 was not unfavourable to the public health. The early cessation of the rains in the previous year, although disastrous to the crops, was followed by a long period of unusual dryness and a period, consequently, characterized by unusual immunity from malarial diseases. There was no rain for the first three months of the year, and only very slight showers fell in April and May, except in one district. In June the monsoon set in, and continued "throughout the country in a very favourable "way." Outside, as well as in, districts declared to be affected by famine, the prices of food-grains were very high and bore severely on the labouring poor, who form the bulk of the population. Plague added to the sickness and mortality arising from high prices and famine; but the loss of life due to it was small when compared with the anxiety which its progress caused, not in the Bombay Presidency only, but throughout India. After all, the 46,944 deaths attributed to plague do not bulk very largely in a total for the year of 749,916, of which 57,109 were caused by cholera, 85,966 by dysentery and diarrhœa, and 405,652 by fever exclusive of plague.

2. The Report deals separately, as it did last year, with the vital statistics of the European and Eurasian population of the Presidency. As we remarked last year, these statistics relate to communities numerically so small that an attempt to draw general conclusions from them might mislead. This is shown by a comparison of the vital statistics of the year under report with those of its predecessor. The population numbers according to the last census, 18,486 Europeans and 8,519 Eurasians, are used in both years as those on which birth and death ratios are calculated. In 1896 the number of births of Europeans was 294, as compared with 259 in the following year; and the returns record that, whilst of the former number 161 were births of male, only 133 were births of female children. This proportion of the sexes was altogether reversed in 1897, when the male children born numbered 119 and the female 138. The death-rate amongst Europeans did not differ much in the two years, having been 15·69 in 1897, as compared with 16·46 in the previous year, per thousand of population. Amongst the small Eurasian community the death-rate increased from 22·89 in 1896 to 28·17 in the year under report. The 44 deaths due to plague account chiefly for this increase. Only 21 deaths from

plague occurred amongst the very much larger European population. The great majority of the deaths from plague amongst both Europeans and Eurasians occurred in Bombay City ; but it must be remembered that more than half the entire population of these two races in the Presidency live in Bombay City.

3. Amongst the native population, numbering 18,820,346, the birth-rate fell from a ratio of 36·76 in the previous year to a ratio of 33·46 per thousand in the year under report ; and the number of deaths exceeded the number of births by 120,223. Instead, therefore, of there being a "natural increase" there was a considerable decrease of population during the year. Other provinces show even greater decrease ; and their case may serve as a warning that, in a country like India, where the effect of famine and pestilence on fecundity and mortality may be a large loss of population in a single year, the practice of estimating the population between the last and next census by adding to the population of each year a tenth part of the total increase which accrued between the last and its immediate preceding census, might sometimes give rather deceptive results. The City of Bombay itself furnishes a striking example of the violent fluctuations in vital statistics which may follow the outbreak of an epidemic. In the year 1896, the recorded birth-rate was 19·35 per thousand of the population : in the year under report it was 11·29. The explanation of this sudden decrease is not altogether to be found in the directly destructive effects of plague, but mainly in the panic which its outbreak caused amongst the inhabitants, and the consequent exodus of a large proportion of them from the town. This exodus led to a very sensible reduction of the population. The decrease of the birth-rate, it may be assumed, was not due, except in part, to the direct influence of sickness on the inhabitants, but to a smaller number of births naturally occurring in a smaller population. Elsewhere in the Presidency, famine and high prices were chiefly responsible for the decrease in the number of children born, as well as for the increased number of deaths. Whilst there were 62,154 fewer births, there were 153,444 more deaths registered than in the preceding year. These results may be taken as mainly due to the privations which the population underwent in consequence of scarcity and high prices following failure of the crops. In the districts declared to be wholly or partially suffering from famine, the decrease in the number of births and the increase in the number of deaths may be accepted as some measure of the distress to which their inhabitants were subjected. In all of the five famine-stricken districts the deaths exceeded in number the births. For example, in Satara the birth-rate was 31·51 whilst the death-rate was 54·92 ; and in Sholapur the former was 30·77 whilst the latter was 50·89. In each of the other three the number of deaths exceeded the number of births. If with these the birth and death rates in districts not overtaken by famine are compared, it will be seen that in the latter the number of births, as in normal years, generally exceeds the number of deaths. In the Surat district the recorded birth-rate was 40·64 and the death-rate 38·88 ; whilst in Broach the former was 42·39 and the latter 34·63. Instead of registration of vital statistics having deteriorated during the year under stress of plague and famine, the Sanitary Commissioner says this "has been well carried "on in most of the areas owing to the exigencies of plague and famine. The low death-rates under "25 per 1,000 are mostly shown in the talukas of Sind and the Gujrat Registration District." In the Collectorates of the Sind registration district, more especially, registration has always been, and still continues to be, very defective. Two of these Collectorates return death-rates of less than 20 *per mille* of population.

4. *Chief Diseases.—Cholera* caused 57,109 deaths. It prevailed in the end of the preceding year and continued until the end of the year under report. There does not appear to have been anything very exceptional in its course. Its fatality increased rapidly from March until it attained its climax in July, in which month 14,749 deaths were attributed to it. After this, the disease died down, slowly at first, and afterwards more rapidly, until in November only 392, and in December 121 deaths were recorded against it. The first two and the last three months of the year were, as often happens, those of least mortality. In these five cold-weather months only 3,475 of the total number of deaths took place. The disease was most fatal in the famine-stricken districts. In some of the latter the death-rate due to it was very high. In Satara this rate was 9·03 per thousand of population, and in Poona 8·61, as compared with 3·03 for the Presidency as a whole. Of the 220 rural circles 138 suffered, and of the 56 town circles 41 suffered. It is worthy of note that the military cantonments, in which the sanitary arrangements may be assumed to be more complete than in native towns and villages, showed no comparative immunity from cholera. Six out of the eight in the Presidency were attacked. From numbers so small, however, it would be unsafe to draw conclusions.

5. *Small-pox* mortality was less than in the preceding year, and only slightly exceeded the decennial mean. The death-rate for the Presidency was only 0·20 per thousand of population. Of the deaths, 29·46 per cent. occurred amongst children under one year of age, and 46·39 between one and twelve years of age. The year 1897–98 was an unfortunate one for vaccination. The numbers vaccinated showed a net decrease in primary cases of 7·42, and in re-vaccination of 15·36 per cent. "In total "operations there is a decrease of 66,073, or 8·87 per cent." The causes of the decrease were mainly the prevalence of plague and famine. "The exodus from large towns," writes the Deputy Sanitary Commissioner of the Central Registration Circle, "owing to the presence of plague, interfered greatly "with vaccination work in them. Some of the Inspectors and Vaccinators were engaged on plague "duty." He adds :—"Owing to the absence of the people from their villages during the famine, the "usual number of children for inspection could not be obtained." In paragraph 7 of the Vaccination Report, a table is given showing the numbers vaccinated in the Native Army. In this table the number of persons primarily vaccinated in the Native Army is stated to have been 3,384. It is not said that these persons were all sepoys. In India generally, it is somewhat unusual to find natives who have reached adult life without having had an attack of small-pox, unless they have previously been protected against attack by vaccination or inoculation. Under these circumstances the number given in the table seems large, if it refers to sepoys who had never previously been vaccinated, inoculated, or had small-pox. Possibly, men who may previously have had small-pox, or been inoculated, but have not been vaccinated, may be entered as cases of "primary" vaccination. The protection of the infant population is a satisfactory feature of vaccination in the Bombay Presidency. According to paragraph 9 of the Report, 629,693 births were registered during the calendar year 1897,

and during the same year, 136,453 deaths of children under one year of age were registered, leaving available for vaccination 493,240. Of this last number 417,924, or 84·73 per cent. were successfully vaccinated. Of the comparatively small unprotected residue, doubtless a considerable number were found to be unfit to undergo operation, owing to ailments of some kind. The cost of vaccination in this Province is great, averaging 6 annas and 10 pies for each successful case; but with so excellent a record of infant vaccination to show, both the Government and the people get value in protection from disease which well repays the outlay. In a year of famine, where large numbers of people were assembled on the numerous relief works, and when there must have been much wandering from village to village in quest of employment or food, the risks of dissemination of small-pox infection must have been greatly increased, and the comparatively small mortality from the disease was, there can be no room for doubt, largely, if not altogether, due to the protection afforded by efficient vaccination. The Sanitary Commissioner writes :—" The birth and death statistics are taken for the " calendar year, as usual, in calculating the number available for vaccination, because infants are " generally not vaccinated until three months after birth." The percentage of successful cases of primary vaccination, excluding " unknown " cases, was 98·3, and of re-vaccination 79·25. The latter is high, and seems to suggest the need for scrutiny and an exact definition of what constitutes successful re-vaccination. Animal lymph was exclusively used in Bombay City, and its use in the Province generally was extended. The Acting Sanitary Commissioner, who has written the Vaccination Report, remarks in the concluding paragraph :—" The year was a disastrous one for vaccination " work, owing to the effects of famine and plague. In many parts the people were on the move, and " not readily got at, and from many of the large towns there was a large exodus. The death-rate was " high, especially among children, and there was a low birth-rate." He adds :—" The measures taken " for the protection of the famine camps from small-pox were, however, a matter for congratulation, " as vaccination work was carried on systematically in these camps with very satisfactory results. " The attacks from small-pox in these camps were 270, and deaths 20. The figures for the camps " during the famine of 1877 are not available, but the extent of the disease in that year compared with " the present may be judged by the fact that there were 27,369 deaths in the whole Presidency from " small-pox in 1877, while in 1897 there were only 3,835. In addition to the measures taken, this " satisfactory result is due to the good vaccination work which now for some years has been done in " the Presidency." The remarkable contrast mentioned between the small-pox mortality of the two famine years is a good practical illustration of the protective influence of efficient vaccination against small-pox.

6. The number of deaths recorded as due to *fever* includes deaths from plague. Of the latter there were 46,944, and if these are deducted the total of fever deaths fall below the number for the previous year. The same climatic conditions which in other provinces were favourable to a diminution of mortality from malarial diseases, had a similar effect in the Bombay Presidency. The unusual dryness of the first five months of the year under report had the effect of keeping the fever mortality below that of the corresponding months of 1896. During the last six months, after the monsoon had set in, the death-rate considerably exceeded the mean of the ten years from 1887 to 1896. The fever death-rate in the Western Registration Circle, which includes Bombay, was 28·66 per thousand of population. This high rate the Sanitary Commissioner says was chiefly due to the prevalence of plague in Bombay, and adds : " It is quite clear that many plague deaths escaped registration as plague deaths and were " put down to other causes." On the other hand, in the Central Registration Circle, if the 21,667 deaths attributed to plague are deducted from the total fever deaths of that circle, the remainder is less than the number of fever deaths for the previous year. From this it may, to some extent, be inferred that the practice of crediting plague deaths to other causes was not general.

7. *Dysentery and Diarrhœa* had attributed to them 85,965 deaths, as compared with 36,046 in the previous year. The explanation of this enormous increase is the same as that given in the case of similar increase in other provinces which suffered from famine. The diseases are of the class known as " famine " diseases, and their excessive fatality was the consequence of the insufficient and unsuitable food on which large numbers of the labouring classes had to exist during a protracted period of high prices and scarcity. It is more than probable that the large number of deaths credited to these diseases falls considerably short of the actual number. In the Sanitary Report for Bengal, evidence is given in support of the belief that many of the deaths caused by dysentery and diarrhœa are recorded under the head of fever. Dr. Clarkson writes :—" There is no doubt that the large rise " in mortality from dysentery and diarrhœa is due to famine. In areas where famine most prevailed " the mortality is seen to be the highest, and in those areas on the fringe of the famine, such as Thana, " Kolaba, Ratnagiri, Dharwar, and Kanara, the death-rate is also high."

8. Notwithstanding that plague gave abundant opportunities for its study during the year, it can hardly be said that much additional light has been thrown on the origin of the outbreak in India. Whence the disease came or how brought still remains uncertain. Nor has the use of medicines in the treatment of the disease, so far, appreciably influenced the rate of mortality amongst those attacked. Much has been heard of the success of prophylactic treatment by inoculation; but whilst some have claimed that a certain degree of immunity is conferred by this method of prevention, others maintain that its efficiency still remains to be proved. The measures adopted to prevent the spread of plague have been modified from time to time in accordance with the experience acquired in carrying them out. They have been costly, and have caused much inconvenience and some irritation amongst the people. Doubtless they may have been effectual in retarding or, in some cases, in preventing the dissemination of the disease; but it is only two evident that, in spite of them, plague has found its way into nearly every province of India. Some think the measures would have been successful had they been more stringent. There is a point in the stringency with which they can be applied in India, when further stringency would probably defeat the purpose for which they were devised. One of the methods of dealing with outbreaks, regarding which all are probably unanimous, is the prompt and complete evacuation of infected towns and villages. Unfortunately, in the case of great cities like Bombay and Calcutta, such a method in its entirety would be impracticable; but where practicable and properly carried out it has perhaps rarely if ever failed to be of decided benefit, or even to be completely successful.

9. *Sanitary Works.*—We miss from this Report Statement No. XI., showing the chief sanitary defects in the municipalities of the Presidency and the measures adopted for their remedy. In their preliminary remarks the Sanitary Board state :—" The year under report does not show any " great progress in sanitary work. Owing to the special measures taken by Government due to the " plague, the ordinary sanitation of towns and villages has been much better looked after, and the " general state of cleanliness is probably better than it has ever been, and the Board hopes that this " state of things may continue after the plague has passed away ; but unless municipalities are dealt " liberally with as regards plague expenditure, many projects will be delayed indefinitely for want of " funds." It is satisfactory to learn that sewage farming is making progress. The municipality of Karachi, instead of wastefully discharging the town sewage into the sea, utilises it on a farm " which " is a remarkable instance of the success, both financially and from a sanitary point of view, of Broad " Irrigation carried out intelligently and under proper supervision." The example thus set by Karachi could no doubt be followed by many other municipalities. By way of contrast, a remark may be quoted from paragraph 26 of the Board's Report concerning the disposal of sewage at Poona. " That sewerage is a necessity can be seen by visiting the spot where the foul-smelling sullage is " discharged from carts into a small stream which joins the stretch of water above the Jamsetj Bund ; " and this piece of the river is becoming very foul."

10. *Summary.*—Famine and plague combined to raise the death-rate and lower the birth-rate. The number of deaths exceeded the number of births by 120,223. Climatically regarded, the year was not an unhealthy one. The unusual dryness of its first months, consequent on the early cessation of the monsoon of 1896, had the effect of lessening the prevalence of malarial diseases. Fever during the first five months was less fatal than in the corresponding months of the preceding year. Although high prices prevailed everywhere, famine was officially declared to exist only in five districts, and scarcity, not amounting to actual famine, in four others. The famine-stricken districts show the effects of the privations which their populations endured by their high death-rates and their generally low birth-rates. Cholera carried off 57,109 victims. There was nothing very unusual in its history. The two first and the three last months of the year were those of lowest cholera mortality. Some of the famine-stricken districts suffered severely. The Presidency enjoyed a remarkably immunity from small-pox mortality in a season apparently favourable to its spread, a season in which there were large collections of people employed on relief works, and in which there was much wandering of destitute persons from town to town and village to village. It is safe to attribute this freedom from unusual small-pox mortality to efficient vaccination. The deaths numbered only 3,835, a number in striking contrast with the 27,369 recorded in the previous famine year of 1877, before vaccination had reached its present state of efficiency. Next to lessened mortality from small-pox, perhaps the best measure of the efficiency of vaccination is the proportion of the infant population annually protected. In the Bombay Presidency, 84·73 per cent. of the children under one year of age were successfully vaccinated. In the neighbouring Presidency of Madras, this proportion was only 31·8 per cent., excluding municipalities, and the death-rate from small-pox was 0·7 per 1,000 of population, or more than three times the Bombay rate of 0·20. Bowel complaints were very destructive of life as they usually are in seasons of famine. Plague accounted for 46,944 deaths, and, in spite of the measures taken to prevent its spread, was carried to many and distant parts of India. Although the expenditure due to the combat with plague and famine crippled the resources of the Province, the dread of a visit from plague doubtless aroused both urban and rural authorities to the need for sanitary improvement. The result has been that, in the opinion of the Sanitary Board, the general cleanliness of both towns and villages is probably better than it ever was before.

9th June 1899.

No. 12.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner for the Hyderabad Assigned Districts for 1897.

The acute distress following the scarcity which prevailed during the preceding year continued until the autumn crops had been reaped in 1897. A long period of high prices and hard times had enfeebled the people and made them fall easy victims more especially to fevers and bowel complaints. " The maximum temperature was above the mean but below that of the previous year " ; whilst the rainfall exceeded that of the previous year by about six inches and was below the average of the preceding ten years by about the same amount. The price of *jowari*, the staple food-grain of the province, stood at 22 seers per rupee in September 1896, and rapidly rose until in November it was more than double. After a slight fall to nearly 12 seers in January of the year under report, the price again increased until it reached its highest point in August : in this month only a little over seven seers could be bought for a rupee. The movement in the price of *jowari* during the period of famine is well shown in the diagram on page 10 of the report. The public health could not but suffer under the conditions described. "The death-rate of the year was 52·6 per 1,000, or 33 per " cent. in excess of the quinquennial average. The main cause of the high mortality was the famine " —that is to say, local scarcity and high prices combined with immigration of starving people from " the Central Provinces."

2. *Vital Statistics.*—Much attention continues to be bestowed on registration in Berar ; and the birth and death rates show that it is not bestowed in vain. During the year under report the recorded birth-rate was 39·7 and the death-rate 52·6. Of nearly five thousand registers inspected by

district authorities, 4 per cent. were found to be defective. But it is evident from an examination of the proportion of registers found to be defective by the different officers, that the strictness of the scrutiny to which the registers were subjected must have varied considerably. Whilst Deputy Commissioners detected defects in 8·5 of the registers examined by them, Attachés, Assistant and Extra Assistant Commissioners detected only 1·6 per cent. Even a greater difference is seen to have characterised the testing of registers in the different districts. In Wún, out of 895 tested 84 were found to be defective, as compared with only three out of 483 in Ellichpur. The number of births and deaths found by the district authorities to have been omitted from the registers is not given. In upwards of three thousand registers examined by Superintendents of Vaccination, omissions were discovered in 5·4 per cent.; and the number of births and deaths found by them to have been omitted was 218 of the former and 131 of the latter. In municipalities more attention is said to be given to registration. The table on page 3 shows that in municipal towns there were 128 prosecutions for failure to register births or deaths. By the persistent efforts made in the past, and still being made, to improve registration, the vital statistics of Berar are attaining to a condition of approximate accuracy. Already, they may be relied on with some confidence to afford valuable information regarding the incidence of disease and the general health conditions prevailing among the people of the province.

3. The recorded *birth-rate*, which was 39·7, varied little in any of the six districts of the province excepting Basim, in which, owing, as the Sanitary Commissioner thinks, to defective registration, it was only 37·0. It tends to increase confidence in the substantial correctness of the registration of births to find the recorded proportion of male to female children born to be 106·7 of the former to every 100 of the latter. "In August the registered births fell below the mean and remained below it "during the remainder of the year." The months of August, September, and October are those in which the highest number of births is usually recorded; but in the year under report there was a diminution below the average recorded in the last five months of the year. Here again, there can be little question that the birth registration is consonant with the facts, and that the distress which prevailed during the last months of 1896 and was prolonged into the year under report led to a falling-off in the birth-rate. "The results of our inquiries," writes the Sanitary Commissioner, "at "relief camps and poor-houses went to show that pregnancy was a rare condition amongst the women "driven by famine pressure to these centres of relief." This is in accordance with general observation under similar conditions in other provinces.

4. The *death-rate* was 52·6 *per mille* of population, and has been but once exceeded in Berar, and then only in the famine year of 1878, when a rate of 81·5 was recorded. The death-rate in the several districts shows no such uniformity as the birth-rate. In Amraoti it was 61·1, in Basim 43·5, and in Wún 42·1. "The high *death-rate* in the Amraoti district as compared with others, is to be "explained by the fact of its situation as regards the Central Provinces, from which territory the "starving poor flooded the district, seeking for work and food. Numbers of these persons died from "the effects of chronic starvation, from which they suffered before reaching Berar, with the result of "unduly raising the death-rate." The mortality in towns was similarly swelled by the influx of numbers of famine-stricken persons attracted by the arrangements made for the systematic administration of relief. The one exception to a record of a high death-rate in towns was Ellichpur; and in this, the remarkably low rate "is only attributable to defective registration." As is usual under similar conditions, the very young and the very old suffered most. Children under one year of age died at the rate of 378·4 per 1,000 of those living at that age; and persons exceeding 60 years of age at the rate of 138·7. Persons of from 10 to 20 years suffered least. The aboriginal tribes in Berar, as in the Central Provinces, died in great numbers, and, doubtless, from a like cause. Living in places difficult of access, of timid and shy disposition, their effectual relief when overtaken by famine was a matter of the utmost difficulty. The provincial mortality during the three months of August, September, and October, was very great, and fell but little short of the total mortality of the other nine months of the year. "Out of a total rainfall of 34 inches 7 cents., 30 inches fell in the "months of July, August, and September, and the resulting atmospheric vicissitudes, accelerated the "fatal ending to which numbers of the half-starved wanderers in our poor-houses were hastening."

5. *Chief Diseases.*—During 1897, as during the two preceding years, *cholera* prevailed with much severity, the recorded death-rate having been 3·5 *per mille* of population, and 4·4 and 4·2 in each of the two previous years. The Sanitary Commissioner predicted that, after the epidemic of 1896, cholera would, in accordance with its usual behaviour, probably be in abeyance during the following year. His anticipations were not fully realized for the province as a whole; but an examination of the returns for each of the six districts shows that the two districts of Wún and Basim which suffered most in 1896 suffered least in the year following. To this extent the Sanitary Commissioner's prediction was fulfilled. The disease was, however, present in every district, and prevailed in 96 registration circles as compared with 97 in the preceding year. We are told that the Civil Surgeons, as usual, submitted detailed reports of the cholera outbreaks in their districts, but that these reports elucidate nothing new in the etiology or mode of spread of the disease. The Sanitary Commissioner adds:—"Suffice it to say that insanitary surroundings and an impure or infected water-supply were "generally shown as associated with these outbreaks." Regarding the use of permanganate of potassium for the purification of wells, we are told that "the general opinion appears to be that this has a "beneficial effect." Such a general statement does not carry very great weight. Exact experiments and observations are still wanting on which to base conclusions as to the effect which the permanganate of potassium treatment of wells exercises in controlling cholera outbreaks. Dr. Roe notices one very practical obstacle in the way of the general employment of this method of water purification. The number of wells in a Berar village or town, he says, makes systematic disinfection almost impossible. The Sanitary Commissioner has introduced, at page 12 of his report, a very useful table to show the total mortality and death-rate from cholera in each district of the province for the year under report, as well as for the 26 preceding years. He says:—"This and similar tables "for the other chief diseases are a useful series for reference and have therefore been retained *in extenso*."

6. The provincial death-rate from *small-pox* was only ·2 *per mille* of population. The disease was more than twice as fatal in urban as in rural circles. A list of towns is given in which a high death-rate prevailed, and the Sanitary Commissioner thinks it highly discreditable to the responsible officials of these towns that this should be so. Considering the distress and sickness which prevailed throughout the province, it is satisfactory to find that not only was there no falling off in the numbers vaccinated as compared with the numbers vaccinated in the official year 1896–97, but that there was a substantial increase of 5,289. The percentage of successful cases in primary vaccination was 96·4 as compared with 96·8 in the previous year. In re-vaccinations the percentage of successful cases was 30 as against 20·5 in the preceding year. The Sanitary Commissioner writes :—"The ratios of 45·9 and 36·9 in the Ellichpur and Buldana districts "are too high. I do not consider them reliable." But if he considers so high percentages to be unreliable, it would be interesting to have his opinion of the corresponding figures for Madras and the Central Provinces. These, for the former, are 81·0, and for the latter 87·87, according to Statement I. of the Vaccination Reports for those provinces. Dr. Little's remarks on this question of the percentage of success in cases of re-vaccination are worth quoting :—"When primary vaccination "has been properly performed, the individual is protected totally or in part against cow-pox and "small-pox, and the amount of susceptibility remaining is generally so slight that in the majority of "cases re-vaccination only results in the development of papulæ, which last but a day or two, or may "produce little more than mere local irritation, which the inexperienced would wrongly record as "successful. Superintendents must be more careful in checking vaccinators' results under "re-vaccination." A satisfactory feature of the season's work is the high percentage of infants protected against small-pox. Of the infants available for vaccination 93·3 per cent. were successfully vaccinated. In another respect the work stands in favourable contrast with that recorded in the contiguous Central Provinces. Whilst in Berar 2,847 persons were vaccinated by each vaccinator during the year, the number in the Central Provinces was 1,391, or less than half. The table given on page 4 of the Vaccination Report shows the mean death-rate from small-pox for quinquennial periods beginning with the year 1868–69. The mean for the first quinquennium was 2·02, for the second 1·56, for the third 0·58, for the fourth 0·38, for the fifth 0·2, and for the last 0·19. Dr. Little may well say : "The above figures tend to prove the axiom that in countries where there is much "vaccination and re-vaccination relatively to the population, there is but little small-pox."

7. *Fevers* were not greatly more fatal than during the preceding year, and were somewhat less so than during 1894 and 1895. Their seasonal incidence did not much deviate from the normal, the greatest number of deaths taking place in the autumn months. As in the famine of 1878, "the "enfeebled condition of the people due to insufficient food caused them to die in unusual numbers "during the monsoon months when malaria was rife." But fortunately the destruction of life caused by fevers in the famine year under report was small in comparison with what was caused by them in 1878. In the former year the ratio of deaths from fevers was 23·0, and in the latter 38·9 per thousand of the population.

8. *Dysentery and Diarrhœa*, the scourges of the ill-fed and famine-stricken, were, as might have been anticipated, unusually fatal. We have to go back to the famine year of 1878 to find so high a death-rate from these diseases. In 1897 the recorded rate was 10·3 as compared with 6·2 in the previous year, and with 12·6 in 1878. "The famine distress in itself is sufficient," writes the Sanitary Commissioner, "to account for the great increase of mortality under this head, as diarrhœa and "dysentery are the usual ending in chronic starvation." Dr. Little finishes his report with a valuable account of the famine regarded from its sanitary and medical aspect. This account will enable any one who may read it, to gather a clear idea of the effects of starvation on the physical condition of the people. The practical lesson which it teaches is the need for early relief, if suffering, inevitably ending in death, is to be prevented. After a certain stage of starvation has been reached, recovery becomes hopeless, no matter what the diet provided, or how careful the nursing, or skilful the medical treatment. "Of all famine diseases, diarrhœa was the most common, due to pathological changes in "the mucous membrane of the intestinal canal, which once seriously affected by degenerative changes "dependent on insufficient nourishment cannot be renewed, and no food, however nutritious, will be "digested or assimilated." As Dr. Roe, the Civil Surgeon of Amraoti, writes of those who had reached this stage of chronic starvation, "Diet seems a matter of indifference, milk and soup having "no beneficial results. In most cases of this kind, death ultimately results from chronic diarrhœa or "dysentery. Some were under treatment (or rather feeding) for months. They eat well and seem "to be fairly well, but they did not put on an ounce of weight."

9. *Sanitary Works.*—During a year in which the resources of the administration were fully employed in the combat against famine, it was not to be expected that sanitary improvements could receive so much attention as in ordinary seasons. Yet, the Sanitary Commissioner writes: "The "rate of sanitary progress in municipalities, though it has been slow, has nevertheless been steady, "and wherever improved water-supply, drainage or conservancy has been effected, it has been "appreciated generally by the people." The chief sums expended on municipal sanitation came under the head of water-supply, drainage, and domestic cleansing. Under the first of these heads close upon 60,000 rupees were expended, whilst upwards of 10,000 were spent on drainage, and nearly 67,000 on domestic cleansing. On district sanitary works, just over a lakh of rupees were spent, and of this amount nearly 43,000 rupees were expended in the single district of Amraoti.

10. Briefly summarised, the history of the year was one of famine, much sickness, and great mortality. Not since the disastrous famine year of 1878 has the death-rate of 52·6 been exceeded. The birth-rate of 39·7, when compared with that of other provinces, was high. Both births and deaths appear to be registered with approximate accuracy, the result of years of persistent attention to registration. Cholera mortality showed some abatement as compared with the mortality for the two preceding years, but was still high. Small-pox was credited with a death-rate of only 0·2 per 1,000 of population. The recorded mortality from this disease shows a steady decrease since 1868–69, from a mean ratio of 2·02 in the five year period commencing with that season, to a mean ratio of only 0·19

in the year 1897–98. This satisfactory result can only be attributed to the progress which vaccination has made in the Province. Fevers and bowel complaints, especially the latter, were unusually destructive of life. The enfeebled condition of the people, resulting from prolonged privation, doubtless led to the high mortality from these diseases. The Sanitary Commissioner confirms what has been taught by the experience gained in previous famines, that, to be effectual in saving life, relief must be given early. After a certain stage of chronic starvation has been reached, no expenditure on diet, nursing, or medical treatment will be of avail. It was not to be expected that sanitary works would make rapid progress during a year in which the resources of the Province were strained to the utmost in relieving distress.

9th June 1899.

No. 13.

Memorandum by the Army Sanitary Commission on the Administration Report of the Town of Calcutta for 1897–98.

The Report was mostly written by Dr. Sen, who officiated as Health Officer during the interval between Dr. Simpson's retirement on the 6th of September 1897 and the arrival of Dr. Neild Cook on the 7th of January 1898. On the influence on the public health of the meteorological conditions of the year no remark is made. The price of food was much higher than the average of the preceding 10 years. This dearness of food no doubt had an unfavourable influence on health, and the death-rate was, with one exception, the highest recorded since 1889. The birth-rate would, of course, be more affected by the price of food prevailing during the preceding year than by its price during the year under report. As a matter of fact, it was practically the same in both years.

2. *Vital Statistics.*—The recorded *birth-rate* was 18·4 per thousand of population; but there are good reasons given for the belief that the registration of births and deaths, but more especially of births, is "ill-performed, owing to its being left mainly, if not altogether, to the discretion of the residents." It is stated that when the parents or friends of newly-born children neglect to present themselves at the ward offices, the births are rarely discovered by the registering officers. It is added that when unregistered cases of births are discovered, prosecutions are instituted against the parties responsible; but, as only 36 such prosecutions were recorded during the year, discovery would not appear to be frequent. How far the low birth-rate in Calcutta is due to defective registration and how far to predominance of males in the constitution of the population cannot be ascertained with exactness: it is most likely due to both causes. An "efficient organisation," the want of which the health officer deprecates, for the collection and record of vital statistics is absolutely essential if the influence of local insanitary conditions on the health of the inhabitants is to be measured with some approach to accuracy. The recorded *death-rate* for the year was 36·1 per thousand of population. The registration of deaths is "better done" than the registration of births. This is probably the case everywhere in India. In Calcutta the accuracy of the death returns depends chiefly on the records kept of the corpses burnt or buried at the cremation grounds and cemeteries. Even this does not secure the record of all the deaths: "a small margin is often "left of cases in which the bodies of the dead are disposed of either at places beyond Calcutta or in "cemeteries in town with which no arrangement exists for the supply of death-returns." The method by which the registration of deaths is effected, whilst securing an approximately correct record of the number of deaths, affords no reliable statistics of the *causes* of the deaths. According to the Health Officer more than half of the people who die in Calcutta are not attended in their last illness by a medical practitioner of any sort, and the causes of deaths reported at the cremation grounds and cemeteries in the majority of instances depend on the mere statement of the friends of the deceased. Altogether, it is obvious that there is urgent need for improvement in the system of registration of vital statistics in Calcutta. A remark made in the 6th paragraph of the report regarding the relative numbers of males and females born, does not appear to be quite accurate. It is stated that "the male births fell below the female births in only three districts, namely, the added "area of Moocheepara, Baniapooker, and Khidderpur": but on referring to the statement of births in the table facing this remark, we find under the heading of "number of births (born alive) during the year 1897," that 54 males were born to 37 females in Moocheepara, 346 to 303 in Baniapooker, and 150 to 122 in Khidderpur. The number of still-births in Calcutta was 979 against 897 in 1896; and gives a ratio of 7·9 still to every 100 live births. This ratio is rather more than half that recorded in Bombay and nearly four times that recorded in Madras. The high death-rate amongst infants, which in past years has constituted one of the most unfavourable features of the mortality statistics of Calcutta, shows no tendency to decrease. As the Health Officer remarks regarding the ratio of 458·5 for the year under report: "These figures serve to show that not only was the "infant mortality in 1897 in excess of the average of the previous five years, but, what is perhaps "of still greater consequence, that the mortality amongst infants has been almost steadily increasing "since 1892." Some of the insanitary conditions which especially affect infant life are noticed, and amongst them those relating to the milk supply of the city. On referring to the account given of laboratory work in paragraph 29 of the Report, we find that of 108 samples of milk analysed 76 were found to be adulterated and two more to be of inferior quality. From this, it would appear that what should be one of the chief articles of a child's diet is rarely procurable in Calcutta of wholesome quality. Where insanitary conditions prevail, the feeblest members of the population,

the very young and the very old, are the chief sufferers. "If the numbers of deaths at different "ages be considered in relation to the proportion of the population at those respective ages, it will be "seen that while the death-rate per 1,000 of the population between the ages of five and sixty is not "excessive for an oriental city, that between the ages of one and five years is at least five or six "times what it should be in a healthy town." The children of the town suffered more severely than those of the suburbs. In the former, of 1,000 children born, 501·7 died within the first year of life, as compared with 394·2 in the suburbs. If their destructive influence on child life may be taken as a measure of their intensity, the insanitary conditions prevailing in Calcutta town are probably almost without parallel in any other large city.

3. *Chief Diseases.*—The number of deaths due to *cholera* showed a decrease, as compared with the number in the preceding year, of 1,100; but was still the third highest recorded since 1889, the first year for which statistics for the city and suburbs combined are available. The death-rate, amounting to 3·4 per thousand of population, cannot but be considered high. The ratio for the Province of Bengal for the year was also high, but fell considerably short of that for Calcutta, having been 2·76. Cholera being declared by many who write about it to be chiefly, or solely, a water-borne disease, the portion of the Report describing the quality of the water-supply during the year is of special interest. In paragraph 5 we are told that "the quantity of filtered water for drinking and other "domestic purposes supplied to the town averaged 30 gallons daily per head of the population. The "supply maintained its general purity throughout the year." It may be concluded from this, that the supply was both abundant and of satisfactory quality. On the other hand, samples of water taken from 63 tanks in different parts of the town were examined, "and all except 5 were found to be unfit for any domestic use." The presence of the *comma bacillus*, it is stated, was detected in only 7·7 per cent. of 839 samples of water from the river, tanks, wells, bathing-platforms, &c. In none of the samples of filtered water was it found. In consequence of the detection of the *bacillus* in the unfiltered water supplied to the bathing-platforms during the previous year, and the synchronous prevalence of cholera, it was concluded that the supply of unfiltered water was dangerous to the public health, and a recommendation made that filtered water should be supplied instead. This recommendation has been acted on, but with what results is not stated. It is certainly the fact that cholera was less fatal during the year under report than during the preceding year; yet the death-rate exceeded the provincial rate and also the mean of the period 1889-96. It is disappointing to find that, although considered by many to be "solely a water-borne" disease, cholera has continued to prevail with persistent severity in spite of the supply of filtered water having been both abundant and of satisfactory purity; and that the mortality due to it exceeds the mortality for the Province of Bengal, in which the water as a rule is neither filtered nor specially protected.

4. *Small-pox* caused 161 deaths as compared with only 69 during the preceding year, and with an average of 469 during the years 1892-96. It appears that all of the 161 deaths recorded did not take place amongst Calcutta residents, 17 of them having occurred in the Campbell Hospital among patients "admitted there from places beyond the limits of Calcutta." The disease cannot be said to have prevailed in very severe epidemic form at any period of the year. In May, during which 37 deaths were recorded as due to it, the disease had attained its climax; and during the remaining seven months of the year only a total of 21 deaths was attributed to it. Of the 161 persons reported to have died of small-pox, 103 were unprotected, 30 vaccinated, and 20 inoculated, whilst one had previously had small-pox. In the remaining seven cases no information as to previous protection, or its absence, was obtained. This statement is suggestive of the persistent activity in Lower Bengal of the inoculator. Where inoculation is practised, small-pox contagion can rarely be absent; and outbreaks of the disease will be frequent unless the population is efficiently protected by vaccination. During the year under report the prevalence of small-pox acted as a stimulus to vaccination, with the result that the number of persons vaccinated was 21,620, or almost twice as great as in the previous year, when it was only 11,976. The increase was chiefly in the number of re-vaccinations, which rose from 2,526 to 8,323. The ratio of success in primary vaccination, calculated on the ascertained cases, was 97·59 per cent. Similarly calculated, the percentage of success in re-vaccination cases was 16·51. Anyone who gives attention to the percentages of success recorded in re-vaccination in the different provinces and cities of India, cannot fail to be struck by the extraordinary contrasts which they present. The record in Calcutta of a percentage of 16·51 of successful cases as compared with 86·97 in Madras city, and with 87·87 in the Central Provinces, seems to suggest difference in the estimate of what constitutes a successful case of re-vaccination rather than difference in the actual results. The Health Officer gives figures to show that few of the children born in Calcutta during 1896 have escaped vaccination, and adds :—"Although the protection of the infant population, so far as the "children born in Calcutta are concerned, cannot be considered altogether unsatisfactory that "protection takes two years time for its accomplishment; so that a large proportion of the population "remains unprotected for over a year from birth. This defect in the due and early protection of the "infant population of Calcutta can only be remedied by a reduction of the period from birth, during "which compulsory vaccination cannot be legally resorted to." In a city from which small-pox contagion is probably seldom absent, the extension to a year of the limit of time within which parents are allowed to keep their children unvaccinated, seems unnecessarily to subject the children to risk of contracting the disease proportionate to the length of time they remain unprotected. The reduction of the age limit for vaccination recommended by the Health Officer would diminish this risk, and, so far as can be seen, would be counterbalanced by no disadvantages to either children or parents. The vaccine lymph used during the year was of three kinds, and of the three, humanised lymph, used in 816 cases, gave the highest percentage of success. Lymph applied direct from the calf gave a percentage of success of 97·32, lymph made into a paste with lanoline of 98·01, and humanised lymph 99·87.

5. To *fevers* and *bowel complaints* were attributed a number of deaths above the average for the previous eight years. The Health Officer observes that, leaving out the year 1895, which was specially unhealthy in respect of fevers both in Calcutta and in the province of Bengal as a whole, the fever "death-rate has risen during the past nine years in almost the same proportion as the price of food,

" giving the high ratio of 14·1 *per mille* of the population, which is not much below half of the total " death-rate in the year 1897, when food rose to a scarcity price." The former Health Officer, Dr. Simpson, traced, also, a relationship between the fever mortality and sewerage system of Calcutta, and endeavoured to show that the benefit to the public health following the drainage of the urban area was gradually disappearing, owing mainly to obstruction to their outfall converting the sewers into sewers of deposit, and to the consequent saturation of the soil with the sewage thus held up and unable to escape.

6. The continued prevalence of plague in Bombay and other parts of India caused much anxiety in Calcutta, and led to the adoption of stringent measures with the object of preventing the introduction of the disease by passengers or goods. It was considered necessary to have all persons arriving in Calcutta by rail from infected provinces medically inspected as soon as possible after their arrival, and to place them under surveillance for 10 days. The ineffectual nature of this " surveillance " soon became manifest, and, in consequence, the Health Officer recommended that " all travellers without exception should be quarantined at the quarantine camps for a sufficient length of time to " remove, so far as possible, the chance of infected persons finding their way to this city and that " there should be also a medical inspection at Howrah and Sealdah of such travellers as passed " through the quarantine camps, as well as a combined medical and police surveillance of all such " travellers in Calcutta for at least 10 days from arrival." Whether effect ever was, or could have been, given to this recommendation is not definitely stated. The inconvenience, hardship, and oppression to which the enforcement of such a measure would give rise in India, could be justified only by its success in preventing the introduction of plague. As a matter of fact plague did not visit Calcutta during the year 1897. Whether this immunity resulted from the measures of quarantine adopted, must be mostly a matter of opinion and speculation. The history of plague during the year following that under report will be of use when the time comes for estimating the effect of the quarantine measures taken for the exclusion of the disease from Calcutta. The Health Department was not unprepared for dealing with plague should it, in spite of all precautions, have obtained entrance into the city. Elaborate arrangements were made for the segregation and disinfection of the infected and for the accommodation and treatment of the plague-stricken in hospitals, even to the disposal of the bodies of those who might die from the disease. To the Health Officer's report a note on " plague precautions " is added by Dr. Neild Cook. Amongst other measures, Dr. Cook strongly advocates prophylactic treatment by inoculation with Haffkine's Plague Serum, and the destruction of rats : " the officers who have most experience of plague are of opinion that the infection " is mostly carried by rats." If this opinion is based on fact, the task of those who would trust to quarantine for the control of plague diffusion must seem a difficult one.

7. Of *sanitary works* in progress during the year the most important were those connected with the two unfiltered-water extension schemes, one for the town area and the other for the suburbs ; and the new drainage works, of which the foundation stone was laid at the end of 1896. It is stated that these important works were vigorously pushed forward, and satisfactory progress made during the year.

8. Briefly, the year, as measured by the death-rate, was not a healthy one. The general mortality was greater than that of the previous year, and exceeded the average of the previous five years. The price of food was much higher than the average of the preceding 10 years, and without doubt had an unfavourable influence on the public health. Good reasons are given for the belief that registration of vital statistics, and more especially of births, is very defective and in need of being organised on an improved system. Perhaps there is no better test of the health of a town than that supplied by its infant death-rate. Measured by this, Calcutta has probably few, if any, equals in unhealthiness amongst great cities. More than half of the male children die in urban Calcutta before they reach one year of age. The death-rate amongst infants of both sexes for urban and suburban Calcutta combined is 458·5 per thousand in the first year of life. In spite of an abundant supply of filtered water for domestic purposes, the cholera death-rate was 3·4 *per mille* of population, and exceeded the provincial rate, which was 2·76. Small-pox was epidemic and caused 161 deaths. Its prevalence acted as a stimulus to vaccination, and the numbers vaccinated increased from 11,976 in the preceding year to 21,620. The percentage of success in re-vaccination cases was only 16·51 : figures in striking contrast with those furnished for Madras City and for the Central Provinces, which give respectively ratios of 86·97 and 87·87. Good reasons are given by the Health Officer for recommending that the period of one year, within which parents are not obliged to have their children vaccinated, should be reduced. The mortality from fevers and bowel complaints was above the average for the previous eight years. Until the drainage scheme in progress has been carried out, marked decrease in the mortality from these diseases is not expected. Fortunately, Calcutta escaped a visitation of plague during 1897. To what extent it owed its immunity from the disease to the quarantine measures adopted to keep out infection cannot be exactly determined. Sanitary works on a vast and costly scale are being vigorously pushed forward.

No. 14.

Memorandum by the Army Sanitary Commission on the Administration Report of the Madras Municipality for 1897–98.

The year 1897 was healthier than its predecessor. Whilst the birth-rate remained nearly the same as in 1896, showing a slight increase, the death-rate fell considerably. The most marked meteorological features of the year were excess of temperature and abnormal rainfall. From the 15th of October until the close of the year, only 9·43 inches of rain were recorded against an average of 26 inches. The high prices of food, which commenced in 1896, continued during the year under report, causing much distress amongst the poorer classes, "and exercising a potent influence on their mortality." The table given in paragraph 184 of the Report shows the very high rates which ruled throughout the year, more especially in the price of second-quality rice and of *ragi*, the ordinary food grains of the poor.

2. *Vital Statistics.*—A birth-rate of 41·3, and a death-rate of 35·5, show that the registration of vital statistics in the City of Madras is carried out with probably a close approximation to accuracy. The constrast between the rates of births and deaths in the City and in the Presidency as a whole, is very striking. Whilst, as just stated, Madras City records a birth-rate of 41·3 *per mille* of its population, the Presidency records a rate of 28·7 ; and whilst the former records a death-rate of 35·5, the latter records a death-rate of only 25·4. As stated in the Report, increase in the number of births during the year, slight although it was, "must be received with satisfaction, considering the distress induced "by famine, which was felt in the town as well as in the Presidency. The birth-rate of a population "being directly influenced by its prosperity and adversity, it would not have been surprising if a "considerable reduction in the birth-rate had occurred." The contrast between the birth-rate recorded for the City and that recorded for the Presidency is sufficiently striking ; but, when compared with 11·36 recorded in Bombay during the same year, it shows to what extent "adversity" had overtaken the latter city. For Madras, only 2·2 still-births to every 100 live-births were registered ; but the President of the Municipal Commission thinks the ratio is unquestionably too low for a city like Madras. In Bombay, more than 14 still-births were recorded for every live-birth ; so, if the ratio is understated in Madras, it is probably overstated in Bombay. The proportion of male children born approximates very closely to that of female children born, having been 101·5 of the former to every 100 of the latter. This approximation may be accepted as some proof of the accuracy of the registration in Madras. As a rule, in India the divergence in the relative number of male, as compared with female children born, increases directly as the defective nature of the registration. The decrease in the death-rate was mainly owing to less mortality from fevers and bowel complaints. Probably the decrease in the fatality of these diseases was, in part at least, owing to the comparative dryness of the latter months of the year. As already stated, the rainfall between the 15th of October and the end of the year amounted to only 9·43 inches as compared with an average of 26 inches.

3. *Chief Diseases.*—Although it prevailed in epidemic form, small-pox cannot be said to have been excessively fatal. The 114 deaths caused by the disease, represent only a death-rate of 0·2 *per mille* of population. Of these deaths, 91 occurred amongst unvaccinated persons, and 13 amongst persons said to have been vaccinated but who had no marks; whilst 10 occurred amongst those who had previonsly been vaccinated. Of the 149 unvaccinated persons who were attacked 91, or 61·0 per cent., died ; whilst of the 44 vaccinated persons attacked only 10, or 22·7 per cent., died. Owing to the high proportion of the population protected in the City of Madras by vaccination, the small-pox epidemic does not seem to have got out of control. The greatest number of deaths due to the disease in any one month took place in August, when 15 persons died of it. In September it caused only eight deaths, and only a total of nine deaths during the remaining three months of the year. Vaccination, re-vaccination, disinfection of the houses and clothing of those attacked, and, when practicable, isolation of the affected, appear to have kept the disease in check. It is curious to find in some reports the outbreak of small-pox assigned as one of the reasons to account for a decrease in the number of persons vaccinated. If vaccination is the efficient prophylatic against small-pox disease which it is proved beyond reasonable doubt to be, it might be expected that, in the presence of a danger against which it is a protection, people would have recourse to it more readily than when such danger is less imminent. In Madras during 1897–98, a year of epidemic small-pox prevalence, the total number of cases of vaccination increased from 27,021 in the preceding year to 33,082, "and the increase was chiefly "due to the prevalence of small-pox in an epidemic form during the latter part of the year under "review." The thoroughness of the system of verification of vaccination in Madras may be gathered from the following quotation from the Report :—"During the year 1897–98, 1,991 cases voluntarily "resorted to the Vaccine Depôts for the inspection of the vaccinator, and in 24,410 cases the results "were verified by the Divisional Vaccinators under Byelaw 11, and, after inspection, certificates of "success were issued to the parents or guardians at their own houses. These results were again "inspected by the Deputy Inspector and four Assistant Deputy Inspectors." Under the revised vaccination byelaws, which have received the sanction of the Government and come into force on the 1st April 1898, the parents of children are bound to produce the vaccinated children at the Depôts for the inspection of the vaccinators. There was a very considerable decrease in the number of persons prosecuted for failure to comply with the vaccination byelaws as compared with the number in the previous year. The results in the case of the 424 prosecutions instituted were that, 316 of the children were vaccinated, in 19 cases vaccination was postponed on account of illness, 36 had left the town, in 48 of the cases proceedings were withdrawn, in two the parents were warned and discharged by the magistrate, and three of the children died before the date fixed for hearing in the Court. The President thinks that "in the majority of the cases prosecuted the fines were inadequate, varying "from 4 annas to 1 rupee, which did not act as a deterrent." He adds :—"The consequence is that "people do not resort to the Vaccine Depôts with their children within the period specified in the

" notices served on them, but wait till prosecution is actually instituted." According to Statement No. I., showing the particulars of vaccination, the percentage of successful cases in primary vaccination was 99·56, and in re-vaccination 86·97. As regards the high percentage of success recorded in re-vaccination, the Health Officer has been requested by the Government to examine 1,000 cases as a test of the accuracy of this record, and to report on the result obtained. At the time the Report was written the whole of the 1,000 cases had not been examined. The total number of births registered in 1897–98, including still-born, having been 18,799, when the 362 still-births and the 5,100 deaths of children under one year are deducted, 13,337 would remain available for vaccination. According to Statement No. I., 15,083 children under one year were successfully vaccinated. The number successfully vaccinated was, thus, in excess of the number born in Madras available for vaccination. This is accounted for by the fact that infants born up-country and who resided within the city for more than two months were also vaccinated under the byelaws. Of the total number of infants vaccinated during the official year, 11,300 only were born in Madras, the remaining 4,023 having been born in the country. The percentage of persons vaccinated to population was 7·31, or greatly above the birth-rate, which was 4·13. Looked at from every point of view Madras, for an Indian city, should have a well-vaccinated population. The percentage of infants vaccinated is high —81·50 of the births according to the table in paragraph 152; the percentage of vaccinations to population is high; and, best proof of all, the mortality from small-pox even in a year when the disease prevailed in epidemic form, did not exceed 0·2 per thousand of population. Owing mainly to the increased number of cases vaccinated during the year, the cost of each case fell from six annas in the previous year to five annas and one pie.

4. *Cholera* was credited with 196 deaths, or a ratio of 0·3 per thousand of population. Although above the average of the preceding four years, this mortality cannot be considered high. For the Madras Presidency the ratio was, in the case of cholera, 4·4; and in the case of small-pox 0·7 for the calendar year 1897. The mortality from cholera in Madras City was thus fourteen times less, and from small-pox three times less, than in the Madras Presidency.

5. As usual, *fevers* had a greater number of deaths attributed to them than any of the other chief diseases; but they were less fatal than during the previous year, and the death-rate due to them fell from 13·3 to 12·1 per thousand of population. The causes which favour fever prevalence are known, and " until adequate provision is made for effective drainage, the proper disposal of dead bodies and " refuse of all kinds, the supply of wholesome water and other sanitary requirements of prime " importance, any great reduction in the fever death-rate cannot be expected." If decreasing mortality may be accepted as an indication that the causes which give rise to fever are in course of being removed in Madras, the diminishing death-rate from this disease from 1892, when it was 15·2, down to the year under report, when it had fallen to 12·1, must be matter for satisfaction. As with fevers, so with *bowel complaints*, which depend for their prevalence largely on the same causes as the former, there has been a steady decrease in their fatality since 1892. Of the unhealthiness of a town there is perhaps no more sensitive gauge than its infant mortality, and measured by this Madras cannot be classed amongst healthy cities. Although the death-rate amongst infants fell from 407 of every 1,000 births in the preceding year to 369·6 in the year under report, it is still high and may safely be accepted as indicating the existence of serious defects in the hygienic conditions of the city.

6. Fortunately, although a case of plague was introduced, the disease failed to secure a permanent footing in Madras. As stated in the report, " the precautionary measures adopted against this disease " have formed an important feature of the administration " of the year, and, so far, appear to have been successful.

7. Under the heading " Sanitary Defects," a summary is given of the chief sanitary wants of the city. Drainage remains the most urgent of these, " though a beginning has been made in the right " direction by the connection of a certain number of houses in Mylapur with a sewerage system " which will discharge, *viâ* a pumping station, over a sewage farm just to the north of Mylapur." The sewage farms, it is stated in the Government review of the Report, were worked at a profit of Rs. 33,545 against Rs. 2,851 in the previous year. When practicable, there can be no more satisfactory way of disposing of sewage and other town refuse than by utilising them as fertilisers of the soil. The importance of preserving the ground within the inhabited area from pollution is forcibly put :— " The ground in such places is soaked with organic matter, and, when the ground air is forced out by " a rise in subsoil water, it is hardly surprising that the death-rate takes a leap up. Even the daily " variations of temperature give rise to great movements of the ground air." The improvement of sanitation is no doubt an up-hill task in Madras. Not only has the dead weight of native apathy and neglect to be overcome, but the labour supply difficulty is ever present in a more or less acute form. A sufficient number of scavengers cannot always be obtained, and when obtained they will only work when they choose : " there is no way of making them work if they do not wish to." The water supply will not be satisfactory until it is made continuous, instead of being, as it is at present, intermittent. If all the pipes were kept full " it would then be possible to have all the wells in the " town closed; for it is scarcely possible, infiltrated as the soil is with organic matter, for any of the " wells in populous quarters to contain water that is fit to drink."

8. Briefly, the year was healthier than the preceding one. Whilst the birth-rate remained nearly the same as in 1896, the death-rate fell from 37·8 to 35·5 *per mille* of population. The poorer classes suffered under pressure of high prices of the food grains chiefly used by them. Short rainfall between the middle of October and the end of the year doubtless contributed towards diminished mortality from malarial diseases. The decrease in the death-rate was mainly due to lessened mortality from fevers and bowel complaints. Small-pox prevailed in epidemic form, and was accountable for 114 deaths. Owing to the previous well-vaccinated state of the population, together with the vigorous prosecution of vaccination and re-vaccination during the epidemic period, the disease was held in check and the mortality did not exceed a ratio of 0·2 *per mille* of population.

There was a large increase in the number of persons vaccinated during the year, a result which is attributed to the stimulus given to vaccination by the epidemic prevalence of small-pox. The percentage of infants vaccinated was high, and equalled 81·5 of the births. Cholera was credited with a ratio of 0·3 deaths *per mille* of population in Madras City, as compared with 4·4 in the Madras Presidency. A progressive decrease in the mortality due to fevers and bowel complaints since 1892 is a satisfactory feature of the returns. Although a case of plague was introduced during the year, the disease failed to secure a footing in Madras. A summary is given of the chief sanitary defects still existing. Drainage continues to be the most important of the sanitary requirements of the City. Next in importance is the need for a continuous water supply. Until the latter is provided, the inhabitants will have to go on using well-water, which, in populous quarters, owing to the pollution of the soil in which the wells are sunk, can hardly be fit to drink.

10th August 1899.

No. 15.

Memorandum by the Army Sanitary Commission on the Administration Report of the Municipal Commissioner for the City of Bombay for the Year 1897–98.

The sanitary history of the year is practically the history of the plague epidemic, and of the measures adopted with the object of staying it. The plague, which was first definitely recognised in Bombay about the middle of September 1896, and was credited with a total of 1,936 deaths by the end of that year, prevailed with varying degrees of severity throughout the year under report. The greatest mortality recorded as due to it occurred in February, after which it steadily diminished until it reached its lowest point of fatality in June. During the latter month only 42 deaths were caused by it; but from June onwards to the end of the year it again increased in prevalence, although it was not in any of the last four months so fatal as it had been during the first four months of the year. To those who gathered their knowledge of the progress of the plague in Bombay city from the telegrams and newspaper accounts which appeared daily throughout the year, a record of only 11,003 deaths, equal to a ratio of 13·39 per thousand of the population, will seem somewhat inconsiderable in proportion to the widespread alarm which the disease excited. The accounts of the wholesale destruction of the inhabitants of cities during plague epidemics in former times no doubt led people to expect that the history of the disease would repeat itself in the case of a great and crowded eastern city like Bombay. "Even in 1897," writes Dr. Weir, "with the second recrudescence or epidemic of plague, "followed by a third recrudescence, the total mortality from all causes in Bombay was not as high as "the mortality from plague alone in many places in India."

2. The influence of the plague on the *birth-rate* was more striking than its influence on the *death-rate*. Owing partly to the great preponderance in the population of males, and partly to defective registration, a low birth-rate is a constant feature of the vital statistics of Bombay. In 1896, this rate was only 19·33 per thousand of population: in the year under report it fell to 11·36. In a population of upwards of eight hundred thousand there were only 9,336 living children born. The proportion of still-born children, always high in Bombay, was excessive in 1897. To every 100 children born alive, over 14 were still-born. Dr. Weir offers no explanation of this increase in the number of still-births. The reduction of the population, numbers following the outbreak of plague and the adoption of stringent measures with the object of staying it, would to some extent account for the remarkable decrease in the birth-rate. The exodus of the inhabitants was at one period estimated at not less than a fourth of the population of the city. Although this may have been an exaggeration, and although the fugitives by degrees returned, it is reasonable to attribute to this cause a considerable effect in reducing the birth-rate. The recorded death-rate was 58·28, as compared with 39·84 for the entire Presidency. This rate cannot be looked upon as excessive under the health conditions obtaining during the year. The loss of life caused in the Central Provinces by famine and its consequences was far greater. For the same reason, however, that the birth-rate in Bombay was abnormally low, it is probable that the death-rate is understated. The diminution of the population, already mentioned, cannot but have led to a diminution in the number of deaths in the city proportionate to the diminished population furnishing the deaths. The ratio of deaths which occurred in this diminished population is calculated, not upon the diminished population numbers, but upon the census numbers of 1891. Yet, even when allowance is made for this probable source of error, the mortality in a city of the size of Bombay during a year when plague prevailed in it from beginning to end, was less than might have been expected. To what extent plague mortality was held in check by the vigorous measures adopted by the Health Department up to the end of March, and subsequently by the Plague Committee, must be more or less a matter of conjecture; but there is no reason to doubt that, although some of these measures may not have been successful, their effect, as a whole, was sensibly to control the disease and to lessen the mortality from it.

3. The Health Officer appears to believe that some of the measures referred to had an effect the opposite of that which they were intended to produce. "There are good reasons," he states, "for "thinking that the disease might have reached its *fastigium* on the 9th of February 1898, if the "measures, as was found a month later, had been relaxed. If the concealment of cases had been less, "the epidemic would have decreased sooner, was the belief I expressed. An epidemic can be "irritated as well as a local sore, and the period between the 9th of February and the 15th of March "may be described as the period of panic and irritation. The measures were followed by the conceal-"ment of cases, and concealment led to intensification of type. The conditions existed which it

" would have been necessary to create had it been desired to intensify the disease." Dr. Weir is probably not singular in believing that, in enforcing the measures for the detection of cases of the disease, for the segregation of the plague-stricken or those suspected of having been in contact with them, for their treatment in hospitals ; and, in the event of death supervening, for the disposal of their dead bodies, a point of stringency may be reached when these measures not only defeat their purpose but create the very evils they are intended to remove. On this question no one can be in a better position to express an opinion founded on experience in dealing with plague than Dr. Weir. Elsewhere in his report he says, regarding the progress of the epidemic in 1897 :—" Though the number of " plague cases was less than in 1896, the *total* mortality was *higher*. This implied concealment of the " disease and intensification of the type through concealment. There is no better tribute to the Health " Department in 1896 than that in 1897, with a higher mortality, with an enormously greater " expenditure, and with a vast organisation, *fewer* cases of plague were at that period detected by the " Plague Committee than by the Health Department in 1896. I admit the difficulties of the Plague " Committee. The population was against them, and they had lost the assistance of the medical " profession. It was difficult for them to obtain information, for the people did not call in medical men."

4. Some of the conditions known to have favoured the development and increased the fatality of plague in other cities in the past, exist to a marked degree in Bombay. The area of the city is about 22 square miles, "and on a portion of this there is the most densely crowded population in the British " Empire." So rapid has been the growth of the city " that all the improvements that other cities " have had centuries to complete are not to be accomplished in Bombay in a few years." The valley in which most of the population live in closely built houses is considered by the Health Officer to be " most unfavourably situated " ; but this opinion does not appear to be altogether consistent with the statement which follows :—" In 1895, before the appearance of plague, Bombay was more healthy than " any large city in India, and the chances of life were better than in many European towns." Apart, however, from what may be regarded as conditions inherent in Bombay which are favourable to the development of diseases, there were others which came in with 1896, and left with 1897. The failure of the harvests, following the premature cessation of the rains in 1896, caused much distress over vast areas of India. The consequences, so far as the City of Bombay was concerned, were disastrous, " people struggled here by road from a famine area as far off as Central India. Even previous to the " monsoon some 40 per cent. of the people arriving by sea were classed by an observer as destitute " and sickly. A year of famine provides helpless subjects for epidemics. If it were decided to " select destitute persons susceptible to epidemic diseases, no groups more susceptible or less resistant " than the large number of people who trudged all the way from Central India by road, and who " arrived here either ill or very weak, could be found." Another of the conditions connected with plague prevalence seems to have great importance attached to it by the Health Officer. The future course of the plague epidemic, he thinks, depends on " the multiplication of the rat population and the disappearance of the disease from amongst rats." He adds :—" Till the rats become immune, the " disease must continue to occur amongst human beings wherever it has been epidemic." If the belief is well-founded, and it seems to be supported by much evidence, that mortality amongst rats often precedes outbreaks of plague amongst human beings, and if, further, the death of the rats is due to plague which they are capable of transmitting to human beings, no system of quarantine, or of segregation during plague prevalence, would seem likely to prove effectual if it left out of count the destruction of the rat population. If, as seems to be a matter of wide-spread belief, rats can communicate the disease to man, the risk of infection of ships, more especially, by these animals might be expected to be great. Much curious evidence is given by Dr. Weir in the sections of his Report dealing with the part which rats are supposed to play in connection with the transmission of plague. "The knowledge that *rats* are carriers of the disease is widespread, and is now being " practically made use of by the people who never had cats before, but who now keep and feed *cats*." The question has a very practical bearing on plague prevention, to judge from the following quotation from Dr. Weir's Report :—" In another portion of this Report I have referred to the " influence of house-drainage in preventing the recrudescence of plague. At first, I thought the effect " of drainage was due to the improvement of the generally sanitary condition of buildings, but I have " now come to the conclusion that it is dependent on the closing of rat-holes, and the demolition of " the homes of the rats."

5. The account given of the incidence of plague according to locality and class of the community is full of interest. One would not have expected that "a lower mortality occurred from plague in the surface-crowded portions of the city than in the suburbs." Dr. Weir believes this to be due to " ventilation " : " the chawls in which the poor classes live have often a gully on one side, and into " this gully windows open. In consequence of this there is more air circulation in the rooms in " which they live even in chawls than in the central and dark rooms in old-shaped buildings in the " suburbs, although these buildings may be in the fields or surrounded by open spaces." The influence of ventilation on plague is well shown in the table given in paragraph 112 of the Report. The proportion of deaths to attacks diminishes steadily with the height of the floor from the ground. " The chances of recovery progressively increased from the *first* floor upwards ; from 84 per cent. on " the ground floor to 45 per cent. on the fifth floor the mortality decreased ; and even the people on " the roadside, destitute though they may have been, had a better chance of recovery than those living " on the ground floor. The proportion of mortality to the height of residence indicates the great " influence of exposure to the air in preventing the spread of the disease." Elsewhere, Dr. Weir observes that plague mortality "has generally been lowest in the highest rooms of the highest buildings." From this it may be said to follow that the European community suffered least, because they live in the best ventilated buildings. Amongst Europeans, only 20 deaths were registered from plague ; yet they "not only did not flee the city at any time, but many of them approached the " disease and exposed themselves to contagion in aid of the sick." Next to Europeans, the lowest mortality occurred amongst Mussalmans—5·4 per 1,000. " This cannot be accepted as correct, though " the Mussalman population suffered *less* than many other classes." The highest mortality occurred amongst the Hindu low castes. By class, the mortality fluctuated between 1·7 per 1,000 for Europeans, and 23·9 for low-class Hindus.

6. Regarding the vexed question of the removal of the plague-stricken to hospitals, Dr. Weir gives his views in the following words :—" In the report on plague in 1896 I held that the treatment of the " sick might be modified according to (*a*) the type of the disease, and (*b*) the ventilation of buildings. " I believe the correctness of this view has been established by experience. I can see no reason why " patients ill from plague should not be treated inside the verandahs of buildings when the verandahs " are wide and look on to open spaces, or why in the fair weather, when there is open space outside " buildings, awnings should not be put and patients allowed to be placed under them. There is no " use in evading the fact that the patients would be better placed for themselves and of no more " danger to others under these conditions than in many private hospitals."

7. The other diseases which, next to plague, contributed most to the mortality of the year in Bombay were diseases of the respiratory system, fevers and phthisis. From *small-pox* there were only 57 deaths, or a ratio of ·07 per thousand of population. During a year when the combat with plague might have been expected to monopolise the energies of almost every department, some falling-off in vaccination would not have been surprising. This, however, was not the case. The returns show that 9,765 children under one year of age were successfully vaccinated, whilst only 9,336 live births were registered. In addition, 2,027 children under six years of age were successfully vaccinated and 136 persons over six years. Of re-vaccination there were 469 successful cases against 314 failures.

8. *Cholera* was credited with 1,265 deaths, or 775 more than in 1896 and 1,001 more than the average. The conditions under which it prevailed were not unusual, and were those which Dr. Weir has repeatedly described as accompanying it in Bombay city. According to months of greatest prevalence, it took the same course as in 1896. Its history during the year further confirms Dr. Weir's observation that people living on ground floors suffer much more severely from cholera than those living in upper stories. Of 1,480 cases, as many as 879, or more than 59·39 per cent., occurred on the ground floors. The explanation, Dr. Weir believes to be, " the development of cholera " germs in the muddy or damp ground, or in dwellings around, and the greater exposure of people " sleeping on the ground floor to them." The highest mortality occurred amongst low caste Hindus and Native Christians; and it is notable, as the Health Officer remarks, that the classes who suffered most are probably the classes most careless about their food and water. The disease was also much less fatal amongst the permament population than amongst immigrants. " The mortality according to " place of birth, both last year and this year, shows that a permanent population live under conditions " much more favourable than the masses who come here to sojourn and labour can hope for."

9. Notwithstanding the epidemic of plague, the work of the Health Department was never once interrupted throughout the year. The works for the removal of refuse outside the island of Bombay have been commenced, and " one great danger to the public health will be removed with the removal of the refuse." Progress has been made in the construction of open drains and house connections. The year is described as having been one of distinct progress in house sanitation. Great improvements have been made in house drainage and great improvements in house ventilation. In such a year the expenditure of the Health Department was necessarily enormous. The special sanitary measures in connection with the outbreak of plague alone cost close upon six lakhs of rupees.

10. Briefly, the year was one of pestilence and famine. Plague, which was first recognised in Bombay about the middle of September of the preceding year, continued with varying degrees of severity throughout 1897. Taking into account the size of the city and the nature and density of its population, 11,003 deaths, giving a ratio per thousand of population of 13·39 from plague alone, can hardly be looked upon as very excessive. The Health Officer shows that nothing had a more marked influence on plague than ventilation. Plague mortality varied in accordance with the sufficiency or insufficiency of the ventilation. Europeans, who live in the best ventilated houses, suffered little compared with the other classes of the population, although they not only did not flee the city during the epidemic, but even visited and attended to the needs of those suffering from the disease. The part which rats take in the dissemination of plague would seem to be a question of much importance. If they are carriers of infection, measures adopted for the prevention of the spread of plague, to be effectual, would have to include extermination of rats. The removal of the plague-stricken from their homes to hospitals is not considered by the Health Officer to be generally either necessary or expedient when suitable accommodation is available in the verandahs of their dwellings. Small-pox was in abeyance during the year, and was accountable for only 57 deaths. Cholera was more fatal than usual; but, considering that Bombay was inundated with ill-fed immigrants from famine-stricken districts, 1,265 deaths from it cannot be regarded as a very large number. Next to plague, the diseases which were most fatal were respiratory diseases, fevers, and phthisis. Whilst the death-rate from all causes rose to 58·28, the birth-rate at the same time fell to only 11·36 per thousand of the population. Notwithstanding the epidemic of plague, the work of the Health Department was never once interrupted. Many and important sanitary improvements were carried out during the year.

SALE OF GOVERNMENT PUBLICATIONS.

The under-mentioned Firms have been appointed sole Agents for the sale of Government Publications, including Parliamentary Reports and Papers, Acts of Parliament, Record Office Publications, &c., &c., and all such works can be purchased from them either directly or through retail booksellers, who are entitled to a discount of 25 per cent. from the selling prices :—

IN ENGLAND .—

For all publications *excepting* Ordnance and Geological Maps, the Hydrographical Works of the Admiralty, and Patent Office Publications :—MESSRS. EYRE AND SPOTTISWOODE, East Harding Street, E.C.

For Geological Maps :—Mr. E. STANFORD, Cockspur Street, S.W.

For Hydrographical Works of the Admiralty :—Mr. J D. POTTER, 31, Poultry, E.C.

Patent Office Publications are sold at the Patent Office.

For all publications *excepting* the Hydrographical Works of the Admiralty and Patent Office Publications.

IN SCOTLAND :—MESSRS. JOHN MENZIES & Co., Rose Street, Edinburgh, and 90, West Nile Street, Glasgow.

IN IRELAND :—MESSRS. HODGES, FIGGIS, & Co., LIMITED, 104, Grafton Street, Dublin.

ORDNANCE SURVEY MAPS OF GREAT BRITAIN AND IRELAND :—There are Agents for the sale of these Maps in most of the chief towns. Copies can also be ordered at many Head Post Offices, and through any Bookseller, or from the Director-General Ordnance Survey, Southampton ; or, in the case of Ireland, from the Officer in Charge Ordnance Survey, Dublin.

The following is a list of some of the more important Parliamentary and Official Publications recently issued :—

Parliamentary:

Statutes—

Public General, Session 1899. Price 3*s.*

Second Revised Edition. A. Price 7*s.* 6*d.* each.

Revised Editions. Tables sh. 1899. Price 6*d.*

Statutes in Force. Chronologi. 2 vols. Price 10*s.* 6*d.*

The Statutory Rules and Ord. a local, personal, or temporary character, issue. Price 10*s.* each.

Statutory Rules and Orders. er. With a List of the more important Stat. n Index. Roy. 8vo. Boards. Issued in the ye. Price 10*s.* each.

Statutory Rules and Orders i. Price 10*s.*

Statutory Rules and Orders, urse of issue.

Acts of Parliament, Public and Local and Private, Session 1900. In course of issue.

[H.C. No. 134/1900.] COAL. Tables showing Production, &c. 1883 to 1898. Price 6*d.*

[Cd. 250.] NAVY. BOILERS. Memorandum respecting Water-tube Boilers in H.M. Ships. Price 4½*d.*

[Cd. 223.] FACTORIES AND WORKSHOPS. Annual Report with Appendices. 1899. Price 6*s.* 11½*d.*

[Cd. 281.] WORKMEN'S COMPENSATION. Statistics of Proceedings under Acts for the year 1899. Price 4*d.*

[Cd. 310.] AGRICULTURAL EDUCATION. Distribution of Grants for, 1899–1900. Price 7½*d.*

A. GODLEY,
Under Secretary of State for India

INDIA OFFICE,
October, 1900.

REPORT.

The present Report on Sanitary Measures in India during the year 1898 is prepared for presentation to Parliament. It contains chapters on the health of the European and Native troops, on the health of prisoners in jails, and on the health of the general population ; it also contains chapters on vaccination, on medical institutions, including medical schools and lunatic asylums, and a chapter on sanitary works. Appended to the Report are abstracts of reports by the three principal Sanitary Commissioners in India, and memoranda by the Army Sanitary Commission in England reviewing the several Sanitary Reports for India.

I.—EUROPEAN ARMY.

Sickness and mortality in 1898.

The health of the European troops on service in India in 1898 was much better than in the previous year, though the death-rate was higher than the average (15·16) for the ten years 1886-95. On an average strength of 67,741, the admissions into hospital were in the ratio of 1,437 per 1,000, against 1,557 in 1897, the daily sick-rate fell from 101 to 90, and the death-rate from 22·93 to 20·05. The invaliding ratio (38) was higher by 5 per 1,000, so that the total loss by death and invaliding was equal to 58 per 1,000, an increase of 2 per 1,000 on the previous year.

The Presidential Army system was abolished in 1894, and the whole of the force in India is now designated the Army of India, divided into the Bengal, Punjab, Madras, and Bombay Commands. This organization took effect from the 1st April 1897.

The following statement shows the relative extent of sickness and mortality among European troops in the four Commands during 1898 and the previous year :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.				
			Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
Bengal	1898	20,060	1,484	96	19·54	44	64
	1897	20,113	1,619	113	23·32	41	64
Punjab	1898	18,388	1,558	90	27·63	40	68
	1897	17,190	1,460	93	21·52	22	44
Madras	1898	12,337	1,293	89	8·59	44	53
	1897	12,369	1,354	104	13·10	48	61
Bombay ...	1898	14,612	1,420	86	18·20	29	47
	1897	14,859	1,508	92	14·33	32	46
INDIA ...	1898	67,741	1,437	90	20·05	38	58
	1897	68,395	1,557	101	22·93	33	56

It will be seen from the above statement that of the four Commands Bengal had the highest daily sick-rate and the Punjab the highest death-rate. The Madras Command was again the healthiest, and its death-rate was less than a third that of the Punjab.

The chief causes of sickness in the whole European Army were, as in the year 1897, ague and venereal diseases, the former yielding a ratio of 394 per 1,000 against 395 in 1897, and the latter 363 per 1,000 against 486. More than half (52 per cent.) of the total sickness resulted from these two causes. Enteric fever, as usual, was the chief cause of mortality, and the death-rate from it was 10·17 per 1,000 against 9·01 in 1897. This fever yielded over 51 per cent. of the total deaths.

Groups of stations.

The following table shows the sickness and mortality among the European troops according to groups :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,226	1,168	86	4·08
Burma, Inland	2,654	1,197	79	7·54
Bengal and Orissa	2,381	1,445	81	14·70
Gangetic Plain and Chutia-Nagpur	6,686	1,426	102	21·09
Upper Sub-Himalayan	12,751	1,622	95	22·82
North-Western Frontier, Indus Valley, and North-Western Rajputana.	4,737	1,890	95	32·09
South-Eastern Rajputana, Central India, and Gujarat.	6,011	1,612	99	22·13
Deccan	8,256	1,447	98	11·75
Western Coast	1,522	1,093	83	11·17
Southern India	3,520	1,488	87	11·08
Hill Stations	7,625	1,139	78	20·46
Hill Convalescent Depôts	3,160	1,433	96	13·61

Of the above 12 groups, six returned a higher daily sick-rate than the ratio for the whole European Army, the highest being 102 per 1,000 of average strength in the Gangetic Plain and Chutia-Nagpur group, the South-Eastern Rajputana, Central India, and Gujarat group following with a ratio of 99. The lowest ratio (78) was returned by the Hill Stations group. The death-rate of the entire Army was exceeded by five groups, viz., the North-Western Frontier, Indus Valley, and North-Western Rajputana; Upper Sub-Himalayan; South-Eastern Rajputana, &c.; the Gangetic Plain and Chutia-Nagpur; and Hill Stations.

Of the stations with a strength of over 1,000, five returned death-rates above 20 per 1,000, viz., Peshawar 48·95, Quetta 44·43, Lucknow 30·66, Umballa 26·90, Agra 23·39, and Rawalpindi 20·21.

lera. There was very little cholera in the European Army in 1898. The admissions to hospital from the disease numbered only 17 or 0·3 per 1,000 of average strength, against 117 or 1·7 per 1,000 in 1897, and the deaths fell from 80 or 1·17 per 1,000 to 14 or 0·21. Of the 17 cases Umballa station contributed 10, all being fatal.

ll-pox. Among the whole of the European troops in India there were during the year under notice only 2 cases of small-pox with no death. In the previous year there were 24 cases and four deaths.

rs. From intermittent fever the admissions to hospital among the European troops in 1898 were in the ratio of 394 per 1,000 of strength, identically the same (395) as in the previous year. The death-rate, however, was much lower, viz., 0·30 per 1,000, against 0·41 in 1897.

From enteric fever the admissions rose from 2,214 or 32·4 per 1,000 of strength to 2,498 or 36·9, and the deaths from 616 or 9·01 per 1,000 to 689 or 10·17. Of the four Commands Punjab recorded the highest mortality under this head, viz., 14·74, followed by Bengal with a ratio of 10·47, Bombay 9·92, and Madras 2·27. Among the larger stations with an average strength of over 1,000, Quetta returned a death-rate from this fever of 35·08, Peshawar 24·48, Lucknow 22·57, Agra 16·71, Allahabad 16·03, Umballa 13·19, Mhow 12·01, and Rawalpindi 10·95. As usual, young and unacclimatised soldiers were the chief sufferers; among those from 20 to 25 years of age the death-rate was 13·46 per 1,000, against 12·74 in 1897, while among men between 25 and 30, and from 30 to 34, the mortality was 2·77 and 2·83 per 1,000 respectively. Among

men of less than one year's residence in India the death-rate from this fever was 20·43 per 1,000, among men between one and two years 9·63, and among men between five and ten years' service the rate was 3·72 per 1,000. Of the total, 689 deaths from enteric fever, 74 per cent. occurred among men between the ages of 20–25, and 41 per cent. during the first year of residence in India.

Bowel complaints.

The admissions from dysentery and diarrhœa among the European troops were in the ratio of 57 per 1,000 of strength, or 22 per 1,000 less than in 1897. The mortality from dysentery was in the ratio of 0·78 against 2·53 in the previous year, and from diarrhœa 0·04 against 0·23. Dysentery was most prevalent in the Bengal Command.

Abscess of the liver.

From abscess of the liver there were 102 deaths, yielding a ratio of 1·52 per 1,000 of strength, against 1·29 in 1897.

Plague.

There were nine cases of plague among the European troops in 1898, and two of them were fatal.

Venereal diseases.

Venereal diseases ranked second in the list of causes of admission to hospital; and first in the causes of invaliding. They were the cause of 25 per cent. of the total sickness during 1898, and over 22 per cent. of the invaliding of the European Army of India. The ratio of admissions from venereal diseases per 1,000 of strength was 362·9 or 123 per 1,000 below that of 1897. Regarding this reduction, Dr. Harvey, Sanitary Commissioner with the Government of India, states—"From the reports of medical officers, it appears that this decrease was partly unreal, and due to the widespread adoption of the system of treating venereally-affected men as out-patients; and partly real, and due to the introduction of continuous and more prolonged treatment of the sick, to measures adopted under the new cantonment rules, to the placing of certain bazaars and cities out of bounds on account of the plague, and to the employment of a certain number of men on field service." The admission-rate from venereal diseases was highest in the Madras Command, viz., 438·3 per 1,000, Bengal came next with a ratio of 437·9, Bombay with 352·5, and the Punjab with 268·9, all being lower than in 1897. The number of men constantly sick in hospital from these diseases was 2,202, against 2,992 in the previous year, being equivalent to over two regiments; and the average stay of a case in hospital was 33 days. The deaths from these diseases numbered 17, and the invalidings 569, against 23 and 662 respectively in 1897.

Invaliding

The loss to the whole army by invaliding during 1898 amounted to 2,580 men, equal to 38·09 per 1,000, against 2,258 or 33·01 in 1897. The proportion of invalids to strength was highest in the Madras Command (43·9), followed by Bengal (43·5), Punjab (40·1), and Bombay (29·2). Of the total number invalided, 28 per cent. were discharged as unfit for further service, being 6 per 1,000 lower than in 1897. As regards the influence of age and length of residence in India upon invaliding, 62 per cent. of the total number invalided were under 25 years of age, against 63 in 1897, while 33 per cent. were of less than two years' service, and 83 per cent. were of less than five years' service. In the European Army as a whole 82 per cent. of the total strength had seen less than five years' service.

II.—NATIVE ARMY.

The health of the Native Army of India was also better than in 1897, notwithstanding an increase of influenza and respiratory diseases among the troops.

The ratios of sickness and mortality among Native troops in the six Commands during 1898 and the previous year are given in the following table :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.		
			Admissions.	Daily Sick.	Deaths.
Bengal	1898	25,036	767	35	10·03
	1897	26,644	834	33	9·12
Punjab	1898	42,515	942	35	13·38
	1897	35,454	867	31	13·26
Madras	1898	22,575	683	30	9·92
	1897	23,588	710	32	9·45
Bombay	1898	24,520	870	31	7·79
	1897	26,421	822	27	10·48
Hyderabad Contingent	1898	6,304	474	17	5·08
	1897	6,554	551	19	6·26
INDIA	1898	126,036	816	33	11·07
	1897	129,802	839	31	13·12

Of the five Commands the Punjab again returned the highest rate of mortality. The ratio being also slightly higher than that for 1897. Pneumonia was very prevalent in this force, and the death-rate from it was 6·52 per 1,000, or nearly a half of the total mortality.

The chief cause of sickness in the Native Army was ague, which again caused 41 per cent. of the total admissions. Among the diseases from which the admissions to hospital were higher than in 1897 were influenza, remittent fever, respiratory diseases, and tubercle of the lungs ; while from small-pox, scurvy, cholera, and ague there was a decrease in the admissions. From influenza the admission-rate rose from 5·4 per 1,000 of average strength in 1897 to 8·3. From venereal diseases the admission-rate in the Native Army was only 40·0 per 1,000 of strength, as compared with 362·9 per 1,000 among European troops. Figures under this head are not available for the years before 1877. The ratios run at a much lower level than those of European troops, and only three times since 1877 has the admission-rate reached 40 per 1,000, viz., in 1890 when the ratio was 41·1, in 1897 when it was 40·8, and in the year under notice.

Pneumonia was the chief cause of death in the Native Army, and no less than 34 per cent. of the total deaths were due to it. The death-rate under this head was 3·77 per 1,000 of average strength, against 2·73 in 1897. From this disease the mortality among the Native soldiers was six times as great as that among European troops (0·61 per 1,000). Fevers of all kinds were the cause of 16·4 per cent. of the total deaths, against 54·3 per cent. among the European troops. From ague, remittent and simple continued fevers, the deaths among the Native troops were in the ratio of 1·69 per 1,000, while among the European troops the proportion was 0·73. On the other hand, the death-rate from enteric fever among the Native troops was only 0·13 per 1,000, as compared with 10·17 among the European troops. From cholera there were 42 deaths in the Native Army, equal to 0·33 per 1,000 of strength, as compared with 68 or 0·52 in 1897.

During 1898 there were 94 cases of plague among the Native troops with 58 deaths, against 131 cases and 81 deaths in 1897.

The following statement gives the principal statistics of the Native Army, arranged in geographical groups, for 1898 :— Groups of stations.

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,391	650	26	5·03
Burma, Inland	4,389	952	36	8·89
Assam	1,547	876	40	27·15
Bengal and Orissa	2,905	1,038	40	9·98
Gangetic Plain and Chutia-Nagpur	5,620	695	34	4·98
Upper Sub-Himalayan	13,857	802	32	10·39
North-Western Frontier, Indus Valley, and North-Western Rajputana.	15,492	1,120	39	15·75
South-Eastern Rajputana, Central India, and Gujarat.	11,310	692	26	7·25
Deccan	18,428	689	27	6·29
Western Coast	2,796	775	36	12·88
Southern India	7,920	635	33	12·37
Hill Stations	18,913	1,149	45	14·06

In eight of the 12 groups the daily sick-rate was higher than that for the whole Native Army, and in five the mortality was greater. The highest mortality was that of the Assam group (27·15), which shows an increase of 14·3 per 1,000 on the rate for the previous year. This was mainly due to cholera, the death-rate from which was 8·4 against *nil* in 1897.

Of the large stations with a strength of over 1,000, the following recorded the highest death-rates :—Edwardesabad 40·61, Datta Khel 40·32, Dharmsala 24·33, and Meerut 23·87. The chief cause of death at the two first was pneumonia, and at Dharmsala pneumonia and tubercle of the lungs.

III.—GENERAL POPULATION.

The year 1898 was a fairly normal one from a health point of view. The weather was quieter and more settled than usual throughout the whole year, and in most months was drier than the average. The monsoon commenced rather late, but extended rapidly over the country, and gave more rain than usual to the greater part of India, the only regions of any marked deficiency being parts of the Punjab, Rajputana, and Berar.

Births were registered throughout all the 10 provinces in India in 1898, and the birth-rates varied between 41·0 and 16·1 per 1,000 of population under registration. The best results were obtained in the Punjab, the North-Western Provinces and Oudh, Bengal, Lower Burma, Berar, and Bombay, their respective rates being 41·0, 37·3 35·8, 34·1, 31·3, and 30·9. In the remaining provinces the birth-rates ranged between 29·5 in Assam and 16·1 in Coorg. The North-Western Provinces, Central Provinces, and Lower Burma were the only provinces which recorded a higher birth-rate than in the previous year. The birth-rates, however, exceeded the death-rates in all the provinces except Assam and Coorg, the excess per 1,000 varying between 10·0 in the North-Western Provinces and the Punjab and 1·8 in Bombay. The recorded deaths fell from 7,645,257 or 36·03 per 1,000 of registered population in 1897 to 5,676,833 or 26·56. The decrease in mortality was due to the less prevalence of all the chief diseases, especially of cholera and fever. In all ten provinces the mortality was lower than in the previous year. Cholera deaths fell from 550,768 to 151,509, and the decrease was spread over all the provinces. Only two provinces recorded cholera death-rates of over 1 per 1,000, viz., Assam 2·2 and Madras 2·0. The diminution in the deaths from fevers by 1,155,178 was participated in by all the provinces except Madras and Lower Burma. In connexion with this cause of death the scheme for the sale of quinine at a low price by postal agency continued to be appreciated by the people. In some places, however, there was a falling off in the demand, which was most likely due to the exceptional healthiness of the year.

The deaths from the chief diseases and from all causes in the several provinces were as follows :—

	Cholera.		Small-pox.		Fevers.		Dysentery and Diarrhœa.		Deaths from all Causes.		
	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000 of Population under registration.

The year 1898 in Bengal was exceptionally healthy. The number of births registered in the province fell from 2,625,844 or 36·94 per 1,000 of population in 1897 to 2,543,701 or 35·79, the latter being made up of district rates varying from 43·59 in Murshidabad to 26·87 in Hooghly and 13·98 in Calcutta. The decrease in the provincial birth-rate, Dr. Dyson, the Sanitary Commissioner, attributes chiefly to the effects of the late famine, and the high prices of food-grains during 1897. He says, the number of births was everywhere considerably higher during the last five months of the year 1898 than during the

earlier months. Of the 46 districts there was an increase of births in 13, the greatest advance being in Champaran, where the ratio was 5·41 per 1,000 in excess of the previous year. Only 10 districts returned a birth-rate of 40 per 1,000 and over, the highest, as already stated, being 43·59 in Murshidabad. Calcutta, as usual, occupied the last place with a birth-rate of 13·98, "and must continue to do so," Dr. Dyson remarks, "as long as the disproportion in the sexes of its inhabitants exists, there being 446,346 males and only 234,814 females." It is also stated that a considerable portion of the female population left Calcutta during the plague scare. Only four towns returned a birth-rate in excess of 40 per 1,000, while 12 rural areas recorded rates of over 50 per 1,000, and 38 others over 45 per 1,000.

The total number of deaths registered during the year under notice was 1,888,468 or 26·57 per 1,000, as compared with 2,341,632 or 32·94 in 1897. There was thus an excess of births over deaths of 655,233 or 9·22 per 1,000. The district death-rates ranged from 40·99 in Noakhali to 15·33 in Sonthal Parganas. In urban areas the rate of mortality fell from 35·09 to 27·50, which was made up of ratios varying from 52·84 in Garulia to 9·98 in Maniktola, both towns being in the 24-Parganas district. In rural areas the death-rate fell from 32·83 to 26·52. The great fall in the death-rate was mainly due to the general healthiness of the year, and improvement in the prices of food which enabled the masses of the people to be better fed and thus to resist disease more successfully.

From all the principal diseases the mortality was much less than in 1897. The province was remarkably free from cholera, the deaths having fallen from 196,247 or 2·76 per 1,000 to 65,020 or 0·91, which was the lowest death-rate from the disease ever recorded in Bengal. Cholera was, however, present in every district except Palamau, and attacked 11,307 villages against 29,776 in the previous year. Of individual districts the mortality was highest in Chittagong (7·92 per 1,000), followed by Balasore (3·15), while Puri, where the congregation of pilgrims usually gives rise to a high death-rate, was comparatively free, its ratio being only 0·45 against 9·57 in 1897. As regards the seasonal incidence of the disease in each of the main geographical divisions of the province, the mortality from cholera in Bengal and Orissa was highest in the first five months and the last month of the year. In Bihar the intensity was greatest in April and May, while Chota Nagpur was remarkably free throughout the year, the death-rate never exceeding 0·02 in any month.

From small-pox the deaths fell from 19,655 or 0·27 per 1,000 in 1897 to 14,269 or 0·20 in 1898. The disease was present in all the districts except Jalpaiguri, but the only district in which it can be said to have prevailed in an epidemic form is Puri, which returned by far the highest mortality (5·82), and where the disease is believed to be fostered by inoculation. In no other district did the death-rate under this head reach 1 per 1,000.

About three-fourths of the total deaths were recorded under fever. The mortality from this cause was, however, much below that of 1897, and less than the mean of the past decade. The number of deaths reported to have occurred from fever during the year was 1,419,483 or 19·97 per 1,000 of population, against 1,679,132 or 23·62 in 1897. Out of the 46 districts, 20 recorded a higher fever mortality than the provincial rate, four registering a rate of over 30 per 1,000, Noakhali coming first with a rate of 35·16, followed by Dinajpur 33·43 and Rajshahi and Jalpaiguri each 31·16, all of which, except the last, showed an increase on the previous year's figures. A high fever death-rate in each of these districts is, however, constant, and the only special factor noted was in the case of Rajshahi where waves of unhealthiness of the nature of influenza passed over the district in March, August, and October.

From dysentery and diarrhœa 37,155 deaths were registered, equal to 0·52 per 1,000 of population, against 53,822 or 0·75 in the previous year. "The large falling off in the mortality was evidently due," Dr. Dyson observes, "to the plentiful outturn of crops almost everywhere during 1897, which enabled the people to obtain wholesome food." Almost all the districts that were affected by the famine showed a smaller mortality under this head during the year under notice.

In Calcutta the birth-rate was, as already stated, considerably below that of 1897, viz., 13·98 against 18·46. The year 1898 was a healthy one, and in spite of an outbreak of plague which accounted for 192 deaths, the mortality was much below the average. The registered deaths numbered 20,343 or 29·8 per 1,000 of population, against 24,665 or 36·18 in the previous year. There was a decrease in mortality under all the chief death causes except dysentery and diarrhœa, from which the deaths rose from 2,896 to 3,074. Cholera deaths fell from 2,349 to 665, being the lowest number recorded since the

amalgamation of the suburbs with the town of Calcutta in 1891. There were 85 deaths from small-pox, as compared with 161 in 1897. The deaths from fever fell from 9,619 or 14·0 per 1,000 to 6,160 or 8·8.

North-Western Provinces and Oudh.

There was a great improvement in the public health of the North-Western Provinces and Oudh in 1898. The effects of the late famine had passed away, and there was an unusual absence of epidemic diseases. During the year 1,751,725 births were recorded, being equal to 37·35 per 1000, against 1,458,947 or 31·10 in the previous year. For the first half of the year the birth-rate was very low, but from July onward it rose by leaps and bounds; "and the fact would appear to testify in a remarkable manner," the Sanitary Commissioner, Dr. Thomson, states, "to the rapidity and completeness with which the population of these provinces had recovered from the distress and privation of the past years." Of the total 48 districts 23 showed a birth-rate above and 25 below the average of the provinces. Bulandshahr again headed the districts with a birth-rate of 53·93, followed by Etah 50·48, Budaun 49·26, Almora 47·20, Muzaffarnagar 47·13, Aligarh 47·06, Basti 46·07, and Kheri 45·27. The birth-rate in municipalities was 36·44, against 34·77 in the previous year, and was made up of extremes ranging from 57·32 in Sikandarabad to 7·41 in Mussoorie.

The number of deaths registered was 1,284,319 or 27·38 per 1,000 of population, against 1,897,592 or 40·46 in 1897. There were thus 613,273 fewer deaths recorded than in 1897, or a decrease of 32 per cent. The provincial death-rate, which was made up of district rates ranging from 41·59 in Naini Tal to 19·11 in Gorakhpur, was exceeded in 26 districts. The urban death-rate was 33·41 against 48·55 in 1897. Out of 104 municipalities only 31 recorded more deaths than births. Registration was again tested by local authorities, and the results disclosed an omission of 2·97 per cent. on 202,982 births, and 2·61 on 166,807 deaths; and in cases tested by the Vaccination Department the omitted percentages were 0·87 of births and 0·53 of deaths.

Cholera was much less prevalent than in 1897. The total deaths from the disease numbered only 2,508 or 0·05 per 1,000, which is the lowest mortality since the introduction of trustworthy registration in 1871. In the previous year there were 44,208 deaths, equal to a ratio of 0·94. There were no excessive ratios, and six districts were entirely free from the disease. Fyzabad recorded the highest district rate of 0·43, followed by Bara Banki 0·39. There were no serious outbreaks of the disease in any of the larger towns or at any of the annual fairs, and only 516 villages out of a total of 107,132 were affected. The mortality was lightest in March (52 deaths), and heaviest in October (503) and November (595). The disease again declined in December, when only 238 cholera deaths were reported.

The province was remarkably free from small-pox, and the mortality fell from 87,127 or 1·86 per 1,000 in 1897 to 2,419 or 0·05, which is the lowest rate recorded since 1871, except in 1895, when it was 0·04. No high rates were reported in the districts, and sixteen escaped the disease altogether. Azamgarh headed the districts with 0·22, and among towns Mau came first with 9·97.

The mortality from fever in 1898 was considerably less than in the previous year, the number of deaths having fallen from 1,463,716 or 31·21 per 1,000 to 1,063,596 or 22·67. This shows a decrease of 400,120 or 27·3 per cent. Among the districts, Naini Tal came first with a fever death-rate of 39·19, followed by Bareilly 37·61, Pilibhit 34·2, Saharanpur 33·02, Bulandshahr 32·90, and Mainpuri 32·11. Fifteen other districts recorded ratios above the provincial rate. The mortality reached its maximum in October and the minimum was in February. Dr. Thomson states that the course of the disease was normal and presented no peculiar features.

The deaths from dysentery and diarrhœa during 1898 numbered 23,574, a decrease of 35,248 on the mortality of the previous year, the death-rates being 0·50 and 1·25 respectively. Among districts, Garhwal again recorded the highest ratio of 6·92, followed by Dehra Dun 2·94 and Benares 2·30. In 12 other districts the provincial rate was exceeded.

The provinces were visited by plague during the year. The first case occurred in Jawalapur, a town near Hardwar, on the 9th January. The disease spread rapidly. A gradual evacuation of nearly the whole town was enforced, and a thorough cleansing and disinfecting process carried out, with the result that the disease ceased and re-occupation was permitted in May. A few villages outside Hardwar were also affected.

njab.

The year 1898 in the Punjab was again a healthy one. The number of births registered was 841,869 or 41·0 per 1,000 of population, as compared with 874,623 or 42·6 in 1897. The birth-rate was again higher than that of any other province in India, and was made up of district ratios ranging from 53·8 in Gujranwala and 53·4 in Jhang

to 21·8 in Simla, and 29·8 in Peshawar. In 14 districts the birth-rate exceeded the provincial rate, and 15 other districts recorded ratios between 30 and 40 per 1,000. The provincial birth-rate exceeded the death-rate by 10·0 per 1,000 of population; in six districts the excess was over 15 per 1,000; in 13 by between 10 and 15, and in the rest except Dera Ismail Khan, where the deaths exceeded the births, by less than 10 per 1,000.

From all causes 638,124 deaths were registered during the year, or only 103 more than in 1897, and the death-rate for the two years was the same, viz., 31·05. The highest district rates were reported from Dera Ismail Khan 40·11, Jhang 39·39, Karnal 37·92, Gujranwala 36·85, and Gurgaon 36·53; the remainder varied between 33·91 in Amritsar and 21·27 in Montgomery. With the exception of the outbreak of plague noticed below, no disease of an unusual character prevailed. As regards epidemic diseases, the year under notice was better than the average for ten years.

The province was practically free from cholera, only 33 deaths having been recorded as compared with 622 in 1897. Only two districts were affected, viz., Umballa and Gurgaon. The former returned 31 deaths, of which the cantonment contributed 30. "That the disease should have appeared in," the Army Sanitary Commission observe, "and restricted its spread almost exclusively to, a military cantonment, with its elaborate system of sanitation carefully carried out under expert supervision, seems a little remarkable, and is yet another proof that there is still a good deal in the behaviour of cholera, especially with regard to the conditions which determine its selection of a locality for its operations, in need of being cleared up."

The severe epidemic of small-pox which visited the province in 1896 and caused a mortality of 45,084 and a death-rate of 2·19, which was the highest reached in any year since 1879, diminished in the following year to 16,077 or 0·78, and further declined in 1898 to 4,998 or 0·24. All the districts were affected except Simla, but the disease was most fatal in Umballa, with a death-rate of 1·07 per 1,000, followed by Sialkot, with a ratio of 0·56 per 1,000, and by Kohat with 0·52. Of the total 4,998 deaths from this disease, all but 487 were children between the ages of 1 and 12.

The mortality from fevers was slightly less than in 1897, though it was as usual severe. The deaths numbered 418,206, giving a death-rate of 20·35 per 1,000, against 422,826 or 20·57 in 1897. The provincial rate was exceeded by 14 out of the total 31 districts, the highest being Dera Ismail Khan 32·26, Bannu 27·99, Gujranwala 26·97, Muzaffargarh 26·29, Gurgaon 26·03, Karnal 25·06, Kohat 24·86, and Dera Ghazi Khan 24·26.

From dysentery and diarrhœa 15,747 deaths were registered, or 104 less than in 1897, the death-rate being 0·77 in both years. Eleven districts recorded a higher mortality under this head than the provincial rate, the highest being Simla 1·93, Gurdaspur 1·71, Gurgaon 1·37, Delhi 1·16, and Hoshiarpur 1·10.

Plague appeared in the province in an epidemic form during the year 1897, when 175 deaths were recorded in Jullundur district. In 1898 there were 1,951 deaths from the disease registered, and of these Jullundur contributed 1,563, and Hoshiarpur district 388.

Central Provinces.

The year 1898 is reported to have been the healthiest which the Central Provinces have known during the past quarter of a century. The recovery of the people from the effects of the famine is shown in the increased number of births registered during the year, which aggregated 284,176 or 29·91 per 1,000 of population, against 254,973 or 26·83 in 1897. The increase was distributed over 14 of the 20 districts, the exceptions being Betul, Nagpur, Wardha, Chanda, Nimar, and Burhanpur; and in all the districts but two (Saugor and Damoh) there was an excess of births over deaths. In the previous year, when famine prevailed, there was an excess of deaths over births in all districts except Sambalpur, which was not affected by scarcity or famine at any time. By districts the birth-rates ranged from 45·54 in Nimar and 45·43 in Sambalpur to 22·18 in Saugor. The provincial birth-rate was exceeded in six districts.

The deaths during the year numbered 246,360 or 24·30 per 1,000, against 658,907 or 69·34 in 1897. The mortality in 1897, however, was abnormal and was in great part due to widespread and destructive epidemics of cholera and fever. Still the mortality in 1898 was very low, and fewer deaths were registered than in any other year on record. The provincial death-rate was exceeded in eight districts, with ratios varying between 34·22 and 24·31; in the remaining 12 districts the death-rates ranged from 24·27 to 19·72.

From cholera only seven deaths were recorded during the year, one in Saugor, four in Balaghat, and two in Nagpur, as compared with 57,131 or 6·01 per 1,000 in 1897. "The complete cessation of the epidemics of the two previous years," the Sanitary Commissioner, Dr. Hutcheson, writes, "was very remarkable. The year 1898 coincides with the

quadrennial or quinquennial disappearance of epidemic cholera in the Central Provinces as in 1884–1888–1893. The general physical and other laws which dominate epidemics indicate a cycle in epidemic occurrences."

Small-pox was also considerably less prevalent than in the previous year, and the deaths fell rom 3,647 or 0·38 per 1,000 in 1897 to 1,149 or 0·11. The disease, however, affected every district but four—(Murwara Jubbulpore, Burhanpur, and Mandla),—but in no district did the death-rate reach 1 per 1,000, the highest being 0·49 in Sambalpur. Of the total small-pox deaths 218 occurred among infants and 386 among children under 10 years of age.

The deaths ascribed to fevers numbered 164,999 or 15·68 per 1,000 of population, against 389,335 or 40·08 in 1897. The number of deaths and the death-rate were both much less than in any of the previous years from 1891. The provincial death-rate from fever was exceeded by thirteen districts, with ratios of mortality ranging from 30·01 to 15·81.

From dysentery and diarrhœa the registered mortality fell from 81,092 or 8·53 per 1,000 of population in 1897 to 13,038 or 1·24, the marked decrease being due to the complete disappearance of famine and privation from amongst the people. The lowest death-rate under this head was recorded by Bhandara district (0·15), and the highest by Sambalpur (2·89).

Plague made its appearance in the province, but from the time of the outbreak of the disease in Bombay in September 1896 to October 1898 there were only 16 deaths, all being imported cases. Precautionary measures were adopted to prevent it spreading; it appeared, however, in an epidemic form in the town of Hinganghat in November 1898, afterwards extending to Wardha and several villages in Wardha district, also to the towns of Nagpur and Bhandara before the close of the year, by which time 128 more deaths had been recorded.

Registration of vital statistics is making steady progress in Burma. Births and deaths continued to be recorded in Lower Burma and registration was extended to three more municipal towns in Upper Burma, making 12 towns in all in which full statistics are recorded. Arrangements were completed for introducing the system of registering deaths in selected districts in Upper Burma from the beginning of 1899. In the area under registration in Lower Burma 153,838 births were recorded in 1898, giving a birth-rate of 34·11 per 1,000 of population, as compared with 143,659 or 31·82 in 1897. That there is still much room for improvement is shown in the variations in the district rates, which ranged from 45·24 in Myaungmya to 18·77 in Rangoon. The number of deaths registered was 117,856, giving a death-rate of 26·13 per 1,000 of population, against 118,570 or 26·26 in 1897. By districts the ratios ranged from 18·40 in Mergui to 43·39 in Rangoon.

Of the chief causes of mortality, cholera was much less prevalent than in 1897, and the number of deaths fell from 8,538 or 1·89 per 1,000 to 2,972 or 0·66. All the districts were visited by the disease except Mergui, and only 8 and 12 deaths were reported in the Tavoy and Sandoway districts. Cholera was present throughout the year, the months of greatest mortality being April, May, July, and March. In both years the disease took a downward course from July until December.

Small-pox was considerably more fatal than in 1897, the deaths having risen from 1,950 or 0·43 per 1,000 to 4,826 or 1·07, this being the highest mortality recorded since 1884. Of the 4,826 deaths, 721 or 15 per cent. were infants and 2,628 or 54 per cent. were children over one and under 12 years of age. Only 7 deaths were recorded in the Arakan division, viz., 2 in Sandoway, and 5 in Akyab. The Pegu division suffered most, its five districts returning 2,875 deaths, of which Tharrawaddy contributed 1,737 or 5·12 per 1,000 of its population. Thongwa in the Irrawaddy division recorded the next highest mortality of 845 or 2·53 per 1,000.

Deaths ascribed to fever rose from 51,752 or 11·46 per 1,000 in 1897 to 53,697 or 11·90, being the highest number yet recorded in the province. By districts the death-rate was highest in Akyab (18·48) and Sandoway (18·33). In seven other districts the provincial rate was exceeded, and in the remainder the rates ranged from 10·93 to 7·29. The town death-rate from fever was 8·23, and the rural rate 12·45, as compared with 7·53 and 12·05 respectively in 1897.

The deaths registered under dysentery and diarrhœa during the year aggregated 8,032, giving a death-rate of 1·78 per 1,000, against 8,793 or 1·95 in 1897. By districts the highest mortality under this head was recorded by Thaton 4·95, followed by Rangoon 4·40, Tavoy 4·36; in the remaining 15 districts the death-rates ranged from 2·66 to 0·42.

Registration of vital statistics is still very backward in Assam. The total number of births registered during the year 1898 was 147,889, giving a ratio of 29·46 per 1,000 of population, as compared with 163,617 or 32·59 in 1897. To some extent the falling off was accounted for by the prevalence of sickness in the previous year. The highest birth-rate was again recorded by Goalpara district, viz., 38·18, followed by Lakhimpur 34·02, Sylhet 30·46, and Darrang 30·09, these being the only four instances in which the provincial rate was exceeded, as the rates of the remaining districts ranged from 28·94 in Sibsagar to 18·66 in Nowgong. **Assam.**

There was a great improvement in the health of the province, and the registered deaths fell from 254,093 in 1897 to 181,527. The death-rate was 36·15 per 1,000 of population, as compared with 50·61 in 1897. In no district were so many deaths registered as in the previous year. In the Surma Valley, comprising the districts of Cachar and Sylhet, the average mortality fell from 54·21 to 37·29, both districts recording an improvement. In the Brahmaputra Valley the average death-rate was 34·92, as compared with 46·97 in the previous year. Of the six districts in this division Nowgong recorded the highest mortality of 47·25 per 1,000, followed by Darrang with 42·25, the ratios of the remaining four districts ranging from 39·03 to 25·93. Taking the province as a whole an excess of deaths over births to the extent of 6·69 per 1,000 was reported.

There was a marked diminution in the mortality from cholera, the number of deaths being 11,149 or 2·22 per 1,000, against 33,240 or 6·62 in 1897. The disease prevailed throughout the year and visited every district. The highest district cholera death-rate was recorded by Kamrup (3·39) in the Brahmaputra Valley, followed by the two Surma Valley districts (Cachar and Sylhet), whose rates were respectively 2·57 and 2·50. The average death-rate from cholera in the towns was 1·87 per 1,000, against 2·23 in the country. Among tea-garden coolies who travelled up the Brahmaputra Valley in steamers there were 26 deaths from cholera, against 371 in 1897 ; and among the coolies at the depots, after landing, there where 58 deaths, against 750.

The mortality from small-pox was a little less than in the previous year, the deaths numbering 5,199 or 1·03 per 1,000, against 5,420 or 1·08. The vast majority of the deaths occurred in the Brahmaputra Valley districts, where there is still a very strong objection to vaccination. Out of 4,768 small-pox deaths in these districts, Nowgong contributed 2,871 or 8·34 per 1,000 of population. The next highest mortality was in Darrang, viz., 688 or 2·24. In no other district did the death-rate from this cause reach 1 per 1,000. Of the total small-pox deaths, 18¼ per cent. occurred among infants, and nearly 51¼ per cent. among children between the ages of 1 and 12 years.

More than a half of the year's mortality was ascribed to fevers, including kala-azar. The number of deaths registered from them was 104,963, representing 20·90 per 1,000 of the population, against 144,307 or 28·74 in 1897. The decrease was chiefly in the Surma Valley, where the mortality sank to nearly one-half what it was in 1897. The highest fever death-rate was again recorded by Nowgong district, viz., 34·54. The provincial fever death-rate was also again exceeded by Goalpara (32·99) and Darrang (28·40). As in previous years, the bulk of the kala-azar deaths occurred in Nowgong district, viz., 10,515 out of the total of 16,472. It is doubtful, it is stated, "whether more than one-quarter or one-third of these deaths were really from that disease, as, especially in the Nowgong district, there is a tendency to call cases of malarial fever which end fatally kala-azar." The Sanitary Comissioner (Colonel Carr-Calthrop) is of opinion that the disease appears to be gradually dying away from the province as a whole.

From dysentery and diarrhœa the deaths were one-third less than in 1897, the number having fallen from 23,136 or 4·61 per 1,000 of population to 16,239 or 3·23. In the Brahmaputra Valley districts the death-rates under this head varied considerably ; thus in Goalpara and Kamrup the rates were 0·38 and 0·95 respectively, while in Sibsagar and Lakhimpur they were 6·90 and 8·54. Colonel Carr-Calthrop knows of no difference in the vital conditions affecting the inhabitants of the upper and lower stretches of the great Assam river which could possibly produce such an extraordinary variation in the death-rate.

The number of births registered in Madras Presidency during the year was 911,747 or 27·4 per 1,000, against 935,845 or 28·7 in 1897. The decrease was attributed partly to the influence of famine in certain areas, and partly to deferred marriages during the past three years. Excluding Madras town, which recorded a birth-rate of 41·6, Chingleput again registered the highest ratio of 35·7, and in five other districts the rate was above 30 per 1,000, while in Malabar and Madura the rates were only 18·6 and 22·7 respectively. Among the 59 municipalities, 12 recorded birth-rates over 40 **Madras.**

per 1,000 ; in 31 towns the rates ranged between 40 and 30 per 1,000, and in 14 others between 30 and 20 per 1,000. The mortality in 1898 was less than that of the previous year by 128,417, the deaths having fallen from 827,525 or 25·4 per 1,000 to 699,108 or 21·0. By districts the highest death-rate (45·2) was recorded in Madras City, and it was nearly 10 per 1,000 higher than that recorded in the previous year. In the other districts the mortality ratios ranged from 30·9 per 1,000 in the Nilgiris to 15·6 in Madura. The average death-rate of the towns was 29·8 per 1,000, and that of rural areas 20·3.

Of the chief diseases, cholera was considerably less fatal than in 1897, the number of deaths having fallen from 143,445 or 4·4 per 1,000 to 65,444 or 2·0. All the districts were affected, but the disease was most severe in Tanjore, Trichinopoly, South Arcot, and Kistna, which recorded cholera death-rates of 6·7, 5·5, 5·2, and 2·9 respectively. "These," the Sanitary Commissioner, Dr. King, states, "are the great irrigation centres of the Presidency, and offer good facilities for the transmission of the cholera microbe from village to village by means of lengthy channels that are liable to contamination, by reason of the insanitary habits of the people." In the remaining districts the rates varied from 2·8 in Nellore to 0·01 in the Nilgiris. The average death-rate in municipal and other towns from the disease was 2·1 per 1,000, against 5·0 in 1897, and that in rural tracts 2·0, against 4·3.

Small-pox deaths were reported from all the districts, and the total in the whole Presidency aggregated 20,490 or 0·6 per 1,000, against 21,678 or 0·7 in 1897. Of the districts, the disease was again very severe in Ganjam, which returned 10,838 deaths ; but this is much lower than the mortality (14,515) in the previous year. In no other district did the death-rate from small-pox reach 1 per 1,000. Of the total small-pox deaths, 3,791, or over 18 per cent., occurred amongst children under 1 year of age, and 9,285, or nearly 45 per cent., among those between 1 and 12 years of age.

From fevers the registered deaths fell from 292,292 or 9 per 1,000 of population in 1897 to 248,638 or 7·5. The decrease was chiefly marked in districts that in 1897 had been affected with famine, and was attributed to better nutrition and better resistance to malaria on the part of the people. On the other hand, the fever death-rate in the Nilgiris rose from 17·0 to 22·1 per 1,000, which was the highest rate recorded by any district, and it was accompanied by a fall in the birth-rate. Five other districts had death-rates of over 10 per 1,000, and eight of over 5 per 1,000. Eight of the 59 municipal towns returned fever death-rates exceeding 10 per 1,000, the highest being 14·8 in Cuddapah and 12·5 in Kurnool.

The number of deaths registered under dysentery and diarrhœa in the Presidency was 29,654 or 0·9 per 1,000, against 38,716 or 1·2 in 1897. The decrease which extended to all the districts but five (Madras, Chingleput, Nellore, Salem, and South Arcot), was attributed to improved dietary of the people following the reduction in the prices of grain. Of the districts, Madras came first with a death-rate from this cause of 7·5, against 4·5 in the previous year, followed by Chingleput with 2·6, and South Canara with 2·0 ; three other districts had rates between 1 and 2 per 1,000. Of the towns, Tuticorin recorded the high death-rate of 9·3 per 1,000, followed by Cochin 7·5, Chingleput 6·8, and Coonoor 6·3.

Plague was imported into the Presidency towards the close of the year, and eleven districts were more or less affected. Precautionary measures were promptly taken, and the spread of the disease was, as a rule, successfully prevented. Up to the end of March 1899 the reported seizures of indigenous plague numbered 2,075, and the deaths 1,681.

mbay. In the Bombay Presidency, including Sind, 582,371 births were registered during the year, giving a birth-rate of 30·94 per 1,000 of population, as compared with 629,693 or 33·46 in 1897. Of the 24 collectorates and districts only four recorded higher rates than in the previous year, the remainder showing a decrease. Bombay City, as usual, recorded the lowest rate, viz., 13·08, which, however, was an improvement on 11·29 in the previous year. The number of births recorded was the lowest for ten years. For the first six months of the year the births registered were very much below the normal, but in July and August there was an improvement, and during the rest of the year the births were considerably in excess of the normal. The decrease is ascribed by the Sanitary Commissioner to the breaking up of family life during the famine, to the reduced stamina of the poorer classes, and to the reduced number of marriages.

In spite of the continued and more extended prevalence of plague the total number of deaths registered in the Presidency fell from 749,916 in 1897 to 548,825, and the rate per 1,000 of population from 39·84 to 29·16, which was made up of district ratios ranging

from 64·03 in Bombay City to 11·04 in Hyderabad. The decrease of 201,091 deaths was spread over all the districts except four. Dharwar district recorded the second highest death-rate (63·81), followed by Belgaum with 41·77. Only three other districts, viz., Broach, Nasik, and Surat, had a death-rate above 30 per 1,000. The high death-rates in Bombay City and Dharwar were due to plague.

The Presidency was remarkably free from cholera during the year, and the deaths fell from 57,109 or 3·03 per 1,000 in 1897 to 4,368 or 0·23. Of these no less than 4,054 occurred in Dharwar district. The five districts of the province of Sind were entirely free from the disease during the year, as were also seven other districts. Of the other affected districts Bombay City came first with 104 deaths, followed by Belgaum 97, Kanara 79, and Kolaba 15. In no other district did the cholera deaths reach double figures. Deaths occurred in every month of the year only in Dharwar and Bombay City, the months of greatest prevalence being June, July, and August. Out of 220 rural circles only 27 were affected by cholera, and 14 out of 56 town circles.

Small-pox deaths fell from 3,835 or 0·20 per 1,000 in 1897 to 1,834 or 0·10. All but three of the districts were affected, but in no case did the death-rate reach 1 per 1,000, the highest rate recorded being 0·42 in Khandesh, the result of 618 deaths. According to age, 27·59 per cent. of the small-pox deaths occurred among infants under one year of age, and 51·69 per cent. among children between the ages of 1 and 10.

The deaths registered in the Bombay Presidency as due to fevers greatly decreased during the year, the number having fallen from 452,596 or 24·05 per 1,000 of population in 1897 to 302,515 or 16·07. These numbers, however, include deaths from plague, from which there were 46,944 in 1897 and 86,191 in 1898. "With the agency at our disposal for the registration of deaths," the Sanitary Commissioner remarks, "and in a country where so many diseases are by the people called fever, it is inevitable that many diseases must be returned under the head of fever which do not rightly belong to this heading. This has always been the case, and although these fever deaths cannot be relied on as being all due to fever, they can, when taken for a number of successive years, give an indication as to the prevalence or otherwise of the common fevers of the country." It is stated, moreover, that the carrying out of plague measures in some of the towns of the Presidency has led to very much more accurate registration in them. The average fever death-rate was exceeded in 9 districts, among the highest being 36·81 in Dharwar, 28·08 in Broach, 27·56 in Bombay City, and 24·52 in Panch Mahals. In only four districts, viz., Belgaum, Dharwar, Broach, and Panch Mahals, was the fever death-rate higher than in the previous year, the increase being due, except in the last named district, to a high mortality from plague.

The number of deaths ascribed to dysentery and diarrhœa also fell from 85,966 or 4·57 per 1,000 of population in 1897 to 56,789 or 3·02, a ratio, however, which is still considerably higher than in any of the ten years preceding 1897—a fact which the Sanitary Commissioner considers due to the after-effects of famine. In nine of the 24 districts the average death-rate under this head was exceeded, the highest being again recorded by Sholapur 6·54, followed by Nasik 6·33, Khandesh 5·90, Satara 5·16, and Belgaum 5·10.

From plague 86,191 deaths were reported during the year, giving a ratio of nearly 4·6 per 1,000 of population, against 49,944 or 2·5 in 1897. The outbreak commenced in September of 1896, at the end of which 2,086 deaths had been reported, being equal to a ratio of 0·12 per 1,000. Up to the end of 1896 ten of the 24 districts had remained free of the disease, but in spite of precautions to check its progress, plague extended to all but two (Kanara and Panch Mahals) of the districts by the close of 1897, though some were but slightly affected. In 1898 all the districts were affected but three in Sind. Of the 86,191 deaths, Bombay City contributed 18,130, an increase of 7,893 on the number reported in 1897, and the death-rate rose from 12·70 to 22·49; but the highest plague death-rate during 1898 was 26·43 in Dharwar, the result of 27,764 deaths. An interesting account of the progress of the plague, and of the measures taken to suppress it, will be found in the Abstract of the Report of the Sanitary Commissioner with the Government of India, at pages 103–118.

Berar.

The total number of births registered in Berar in the course of the year was 89,414 or 31·3 per 1,000 of the population, showing a decrease of 23,950 or 8·4 on the previous year. The decrease was attributed to the effects of the famine which prevailed partly in 1896 and 1897. In all the six districts of the province the birth-rates were lower than in the previous year, and ranged from 33·6 in Akola to 28·4 in Basim.

The deaths fell from 150,222 or 52·6 per 1,000 of population in 1897 to 66,806 or 23·4, a lower rate than had been recorded in any year since the commencement of registration

in 1868, except in 1871 and 1873 when the rates were 17·7 and 22·8. The great decrease in 1898 was attributed to cheapness of the staple food-grain (jowari) of the people, the absence of epidemics, and a reduced temperature, humidity, and rainfall as compared with the previous year. The provincial rate was exceeded in four out of six districts, the exceptions being 20·4 in Wun and 21·0 in Basim; but in no district was the rate half so high as in 1897.

There was not a single death from cholera recorded during the year. This is the more remarkable as in the previous year the disease was epidemic in the province, and the deaths numbered 10,122 or 3·5 per 1,000 of population. Since the introduction of registration in the province only on one previous occasion (1873) were no deaths recorded from cholera.

From small-pox, 592 deaths were registered, as compared with 617 in 1897, the death-rate being the same in both years, viz., 0·2 per 1,000. Nearly 73 per cent. of the deaths (431) were registered in Buldana district, and the fewest number (5) in Akola district. Although the disease was present in several towns, it attained serious proportions only in four in Buldana district. About 45 per cent. of the deaths occurred amongst children under 12 years of age, 91 or 15 per cent. being infants under one year.

Under fevers, a mortality of 32,789 or 11·5 per 1,000 was registered, or about half the number registered in 1897, viz., 65,611 or 23·0. By districts the death-rate from fever varied between 14·8 in Wun and 9·4 in Buldana. Every district showed a reduced rate approaching nearly half the rate of the previous year, and only in two districts (Wun 14·8 and Akola 12·1) was the provincial rate exceeded.

The number of deaths attributed to dysentery and diarrhœa fell from 29,549 or 10·3 per 1,000 in the previous year to 9,942 or 3·5. Ellichpur district, as usual, recorded the highest mortality under this head, viz., 5·9, against 16·4 in the previous year. Akola followed with 4·4, which was also higher than the ratio (13·0) of the preceding year. The other district rates ranged from 3·5 in Basim to 0·9 in Wun. "The comparative lowest dysentery and diarrhœa rate and highest fever rate which the Wun district shows," the Sanitary Commissioner writes, "leads to the supposition that in this district deaths from dysentery are reported and classed as deaths from fevers."

IV.—JAILS.

Sickness and mortality in 1898.

There was a marked improvement in the health of the jail population of India during 1898. The only factors militating against the general health of the jails were the legacy of weakly prisoners convicted in the preceding year, and the overcrowding that took place in a number of the prisons. Not only were the ratios of deaths, admissions into hospital, and daily average number of sick less than in 1897, but they were the lowest in the quinquennium ending with the year under notice. The daily average sick per 1,000 of average strength fell from 39·3 in 1897 to 37·3, the ratio of admissions into hospital from 975 to 917, and the death-rate from 39·64 to 25·34. In every province except the Punjab and Coorg the jail death-rate was lower than in 1897, and in four provinces the rates were lower than in any of the previous five years. In Bengal the rate was the lowest on record, and in Bombay it was the lowest since 1887; while in the Punjab it was the highest since 1893. The Punjab death-rate, however, was not high as jail death-rates go; but the fact that there was a considerable rise is disappointing. There was very little cholera among the prisoners, and in no less than six of the provinces the convicts were entirely free from the disease.

The following statement shows the sickness and mortality among all classes of prisoners in the jails and subsidiary jails of the several provinces for 1898, as compared with the previous year :—

Provinces.	1898.			1897.		
	Ratio per 1,000 of Average Strength.			Ratio per 1,000 of Average Strength.		
	Admissions.	Daily Sick.	Deaths.	Admissions.	Daily Sick.	Deaths.
Bengal	1,037	34	22·5	1,083	36	34·4
North-Western Provinces and Oudh.	921	47	28·7	1,019	50	35·4
Punjab	1,373	37	23·5	1,340	31	16·3
Burma	620	32	20·6	596	29	24·0
Central Provinces	1,134	51	34·6	1,233	65	134·9
Assam	1,185	54	36·6	1,255	51	48·6
Coorg	874	23	92·0	479	11	25·2
Madras	578	27	26·2	672	30	47·4
Bombay	756	27	21·3	807	26	35·2
Berar	581	16	14·9	550	16	34·7
India	917	37	25·3	975	39	39·6

Bengal.

The health statistics of the Bengal jails for 1898 are exceedingly satisfactory, the decline in the death-rate being very marked. The admissions into hospital were in the ratio of 1,037 per 1,000 of average strength, against 1,083 in 1897, the average daily sick-rate was 34 or 2 per 1,000 less, while the death-rate fell from 34·4 to 22·5. These results are mainly attributable to the almost entire absence of cholera, and to the reduced number of admissions from malarial fevers and dysentery and diarrhœa. The year being exceptionally healthy also accounted for the reduced mortality of the jails, but "much credit was also due to medical officers for the care bestowed by them on sick prisoners." Among all classes of prisoners there were 427 deaths, and of these 395 were convicts. Several of the jails were overcrowded during the year. The diseases which contributed chiefly to the convict death-rate (22·9) were dysentery 90 deaths, respiratory diseases 64, pneumonia 69, and malarial fever 43. There were only three deaths from cholera, against 46 in the previous year. Of the convicts who died in jail over 30 per cent. were admitted in good health, about 38 per cent. in indifferent health, and nearly 32 per cent. in bad health. Out of 48 jails the average death-rate among convicts was exceeded in 21, the highest being Barasat 75·0, Purnea 63·6, Chaibassa 55·2, Muzaffarpur 50·3, and in five others the mortality rate was over 40 per 1,000, but several of these have only a small population, and two or three deaths cause a high death-rate. In four jails there were no deaths, and in eight there was only one death in each.

North-Western Provinces and Oudh.

The history of the jails of the North-Western Provinces for 1898 not only shows that there was a considerable reduction in the population as compared with the previous year, but that a great improvement had occurred as regards the sickness and mortality in the jails. This is the more satisfactory considering the large number of weakly prisoners who had been admitted in bad and indifferent health in the previous year. The admissions into hospital fell from 1,019 per 1,000 of average strength in 1897 to 921, the daily average sick-rate from 50 to 47 per 1,000, and the death-rate from 35·4 to 28·7. Of the 56 jails in the province there were no deaths in three, and 36 others recorded death-rates below the provincial jail rate. The highest mortality (81·9) occurred in Mirzapur district jail, the result of 27 deaths, 5 of which were due to dysentery and 8 to pneumonia. Chief among the jails with a low mortality was Bareilly Central Prison, with only 10·6 per 1,000 on an average strength of 2,012 convicts. Not a single case of cholera was reported in any of the jails during the year. Of other diseases, dysentery was accountable for 190 deaths against 307 in 1897. From pneumonia there were 135 deaths against 156 ; other respiratory diseases were also less fatal than in the preceding year. The Inspector General believes that "the prevalence and fatality of pneumonia and other respiratory diseases are to a large extent due to previous epidemics of influenza, as a large proportion of the prisoners who are attacked are severely injured in health, and are particularly liable to suffer from diseases of the respiratory organs. Another important factor in the causation of these diseases is the fact that native prisoners cannot be got to wear their clothing at night. In the coldest nights of winter many of the prisoners remove their blanket coats and cotton clothing, and it is impossible to get the barrack overseers to report prisoners who do so." Of the total 923 deaths 872 were of convicts, their death-rate being 28·8 per 1,000 against 35·2 in the previous year.

Punjab.

The year 1898 was unusually unhealthy in the jails of the Punjab. The admissions to hospital per 1,000 of average strength rose from 1,340 to 1,373, the daily sick-rate from 31 to 37, and the death-rate from 16·3 to 23·5. "Speaking generally," the Inspector General writes, "the increased mortality is ascribable to the serious deterioration of health caused among the prisoners by the prevalence of malarial fevers during the autumn of 1897. It is also possible that the robustness of the prisoners received in 1897 and 1898 had been more or less impaired prior to admission to jail by the scarcity that prevailed in the province during the former year." The provincial death-rate was exceeded in 15 jails, the highest being 60·98 in Kohat, followed by Jhang with 40·59. In four jails there were no deaths. Of the total 294 deaths, all but 18 were of convicts, giving a death-rate of 23·95. One of the most unsatisfactory features of the year was the increase in the number of admissions and deaths from dysentery. Of the total 49 deaths returned under this head 19 or nearly 39 per cent. occurred in the Lahore Central Jail. In combating the disease in this jail "the issue of fresh potatoes and onions in the dietary seemed to exercise an excellent influence." The most fatal disease was pneumonia, the deaths from which (68) increased by 30·77 per cent. There was no case of cholera in any jail. Of the total deaths 37·32 per cent. occurred among convicts who had not been more than six months in jail.

urma.

The Burma jail statistics show that the admissions into hospital and constantly sick during 1897 were higher than in the previous year, the ratios per 1,000 of average strength having risen from 596 and 29 respectively to 620 and 32. The death-rate, however, fell from 24·04 to 20·6. The decrease in mortality was more than accounted for by the decline in cholera deaths from 69 in the previous year to three in 1898. Of the 261 deaths which occurred during the year, 252 were of convicts, the death-rate being 20·39 against 24·11 in 1897. Among the other principal diseases dysentery, malaria, and pneumonia were more prevalent and more fatal, other respiratory diseases and tubercle of the lungs were less prevalent but more fatal, while fewer admissions and fewer deaths were due to diarrhœa. Several of the jails recorded high death-rates, notably Shwebo 75·76, Paungde 73·17, Bhamo 68·97, Rangoon (European) 66·67 Moulmein 50·88, and Kyaukpyu 44·44. Much of the sickness and mortality of the Shwebo jail was attributed to sickly transfers from Katha and Bhamo ; and it is stated that in Bhamo jail most of the victims among the Shans and Kachins were in bad or indifferent health on commitment. Moulmein retains its reputation for unhealthiness. Of the 29 deaths in this jail, 19 were from dysentery. The proposed reduction in the number of prisoners in this jail has, it is stated, been carried into effect.

ntral
ovinces.

The vital statistics of the jails of the Central Provinces for 1898 show a great improvement in the health of the prisoners. The figures, however, are still high comparatively, which is explained by the fact that in the early months of the year new admissions were

still in poor health. The admissions into hospital per 1,000 of average strength fell from 1,233 in 1897 to 1,134, the daily average sick-rate from 65 to 51 per 1,000, and the death-rate from 134·98 to 34·6. Only one (Bhandara) of the 19 jails recorded a higher mortality as compared with the previous year. The average death-rate was made up of jail-rates varying from 94·8 in Bilaspur to 9·3 in Narsinghpur. In four jails there were no deaths. All the jails were free from cholera or any other epidemic, and the admissions to hospital from dysentery and diarrhœa fell to about a third of the number in the previous year, and the deaths to about one-eighth the number. All but 7 of the 175 deaths occurred amongst convicts, the death-rate being 35·18, against 138·3 in 1897. Of the total deaths 70 were of convicts who had not been more than six months in jail.

Assam

Among the prison population of Assam the rate of admissions to hospital fell from 1,255 per 1,000 in 1897 to 1,185 in 1898, the daily sick-rate rose from 51 to 54, and the death-rate fell from 48·7 to 36·6. The improvement in the general health is attributed to the influence of increased diet, to the careful selection of prisoners for extra-mural work, to the use of quinine and iron as a prophylactic during the unhealthy months of the year, and to the unremitting attention on the part of superintendents and their medical subordinates to the treatment and proper dieting of weakly prisoners. In only three of the 23 jails was the average strength above 100, viz., Sylhet, Tezpur, and Gauhati, and these three accounted for 38 out of the total 58 deaths. In most of the other jails the average strength was less than 50. As in the previous year many prisoners were admitted into jail in a moribund condition; of the 18 prisoners who died in Sylhet only 5 were admitted in good health, only 2 out of 13 in Tezpur, and out of seven prisoners who died in Gauhati two were admitted in indifferent health, and the rest in bad health. All but seven of the 58 deaths occurred amongst convicts, being in the ratio of 35·43 per 1,000 against 48·14 in 1897. Only two cases of cholera occurred during the year, one at Tezpur, which terminated fatally, and one at Tura; in the previous year there were 11 deaths from cholera. From dysentery and diarrhœa there were 21 deaths, and from malarial fevers 13.

Madras.

In the jails of Madras Presidency the general health of the prisoners during 1898 was particularly favourable. The hospital admission rate fell from 672 per 1,000 of average strength in 1897 to 578, the daily sick-rate from 30 to 27 per 1,000, and the death-rate from 47·45 to 26·2. Cholera was practically absent, only nine deaths having been recorded from the disease as compared with 236 in 1897; there was also a considerable reduction in the number of cases of dysentery, but the rate of mortality (6·04) remained about the same. Pneumonia, on the other hand, was much more frequent and fatal, as were also other respiratory diseases. The highest death-rate was that of Rajahmandry, viz., 193·14, against 123·08 in the previous year. The general health of the convicts at Rajahmandry was very bad, and the mortality under all the chief headings was excessive. Excluding Rajahmandry jail, the provincial death-rate would have been only 18·59 per 1,000. Of the 97 deaths which occurred in this prison, 71 occurred among convicts who had been less than six months in jail. An enquiry was held into the prevalent sickness and mortality of the jail, when it was found that the ailment was beri-beri, "a dangerous endemic infective dropsy." Special sanitary measures were recommended and have recently been adopted, and it is satisfactory to learn that the health conditions have since improved very materially. In none of the other jails with a strength of over 200, except Vizagapatam and Trichinopoly, with death-rates of 49·26 and 31·16 respectively, did the mortality reach the Presidency rate; while in six jails there were no deaths. Of the total 287 deaths convicts contributed 257, representing a ratio of 28·09 per 1,000 of average strength, as compared with 50·49 in 1897.

Bombay.

Although nearly all the jails in the Bombay Presidency were overcrowded during 1898, there was a marked improvement in health of the prisoners as compared with the previous year. The rate of admissions to hospitals per 1,000 of average strength fell from 807 to 756, the daily sick-rate (27) was 1 per 1,000 more, while the death-rate declined from 35·28 to 21·3 per 1,000. Five jails recorded a higher mortality than in 1897, but in no case was there any marked increase; while in several the figures showed a great improvement over those for 1897. Six out of the 17 jails recorded death-rates above the average, viz., Sind Gang 64·4, Shikarpur jail 58·8, Common Prison 52·9, House of Correction 44·5, Dharwar 30·8, and Thana jail 26·7. All but 23 of the total 216 deaths (including 10 in the lock-ups) occurred among the convicts, their death-rate being 22·5 against 37·8 in 1897. The chief causes of mortality were dysentery and diarrhœa 28 deaths, respiratory diseases 49, including 41 from pneumonia, fevers 19, and tubercle of the lungs, &c., 15. In

spite of the prevalence of plague in the Presidency only 37 cases occurred among the prisoners, of which 20 proved fatal. Not a single case of cholera was recorded in any of the prisons. In the previous year there were 41 cholera deaths, of which Thana jail contributed 37, being more than a third of its total mortality of 118·9 per 1,000, as compared with 26·7 in the year under notice. Pneumonia, as usual, was very prevalent in the Sind jails, 109 cases, out of a total of 155, having occurred in them, and 27 of the 41 deaths. The Sind Gang and Shikarpur jails were the chief sufferers, with 13 deaths in each.

The health of the jail population of Berar in 1898 was on the whole satisfactory ; there was slightly more sickness, but the mortality was considerably less. The rate of admissions into hospital per 1,000 of average strength rose from 550 to 581, the daily sick-rate remained the same (16), while the death-rate fell from 34·7 to 14·9. There was no outbreak of epidemic disease in any of the jails, and little cholera. There were only 24 deaths against 66 in 1897. Nineteen of the 24 deaths occurred in the larger jails at Akola and Amraoti, nine in the former and 10 in the latter ; but the highest death-rate was recorded by Basim, 30·6, the result of three deaths ; Ellichpur followed with a rate of 19·5, the result of only one death. All but two of the 24 deaths occurred amongst convicts, their death-rate being 15·28 per 1,000, as compared with 33·12 in 1897.

V.—VACCINATION.

General results.

During 1898-99 there were 6,860,915 persons successfully vaccinated in the several provinces of India, being a decrease of 283,559 on the number of the previous year. To some extent the decrease in vaccination work was due to the withdrawal of some of the officers of the provincial Vaccination Departments for duty in connection with plague prevention. According to age, over $2\frac{3}{4}$ millions (2,841,126) of the total were children under one year of age, and over 3 millions (3,002,771) were children between the ages of one and six years. The proportion of population protected against small-pox by the year's operations ranged from 53·03 in Burma to 26·66 in Madras. In the vaccination of infants the best results were, as usual, obtained in Berar, the Punjab, and Bombay, where 60·31, 59·97, and 49·91 per cent. respectively of the children born during the year (estimated at 40 per 1,000 of population) were protected against small-pox. In the Central Provinces the percentage was 44·61, and in the remainder it ranged from 37·71 in Burma and 33·80 in the North-Western Provinces and Oudh to 7·38 in Coorg.

Statement showing the total number of persons successfully vaccinated during the year 1898–99 :—

Province.	Population among whom Vaccination was carried on (Census of 1891).	Number of Persons successfully vaccinated.	Ratio of successful Vaccinations per 1,000 of Population.	Number of Children successfully vaccinated.		Percentage of Children born during the Year (calculated at 40 per 1,000 of Population) successfully vaccinated.
				Under One Year of Age.	Between One and Six Years of Age.	
Bengal	71,092,411	2,085,904	28·05	502,300	1,359,636	17·66
North-Western Provinces and Oudh.	47,146,033	1,269,493	26·92	637,472	483,106	33·80
Punjab	20,553,982	727,826	35·41	493,085	122,066	59·97
Burma	8,146,855	443,195	53·03	122,895	212,384	37·71
Central Provinces	12,900,386	421,654	31·70	230,220	103,390	44·61
Assam	5,634,258	242,229	40·58	50,389	125,645	22·36

Coorg	173,055	5,098	27·92	511	2,099	7·38
TOTAL	226,807,817	6,860,915	30·24	2,841,126	3,002,771	31·31

Bengal.

The total number of vaccinations performed in Bengal during 1898–99 was 2,147,452 of which 2,085,904 were successful, against corresponding figures in 1897–98 of 2,319,536 and 2,244,716. This shows a decrease of 172,084 vaccinations in 1898–99, which Dr. Dyson states "is due chiefly to the plague inoculation scare, and to the introduction of the six-puncture system of vaccination. The extra two points of vaccination were looked upon by the ignorant masses of the people as in some way connected with plague inoculation, and this retarded the progress of vaccination and accounts for the smaller number of operations performed during the past year." Although there was a decrease in the number of vaccinations for the year as compared with 1897, there was an increase of 155,053 in the triennial average, which shows that progress is being made. The primary operations numbered 2,087,285, of which 97·99 per cent. were successful. According to age, 502,300 of the successful primary vaccinations were of children under one year of age, and 1,359,636 were between one and six years. For the whole province the successful vaccinations were in the proportion of 28·05 per 1,000 of the population. Estimating the births during the year at 40 per 1,000, the percentage of infants successfully vaccinated was 17·66, which is far below that attained in other provinces except Coorg.

Three methods of vaccination are practised in the province—(1) with lymph taken direct from the calf; (2) with calf lymph prepared with lanoline; (3) with human lymph taken by arm to arm transfer. Compared with the previous year's figures there was an increase of 31,082 in the number of primary operations performed direct from the calf. As regards the attitude of the people towards vaccination, Dr. Dyson reports that there

is still much opposition to it in many districts, particularly in Puri and in some of the Behar districts, where "the people are generally averse to vaccination, and look upon inoculation with favour." Another hindrance, he says, is the difficulty experienced by licensed vaccinators in some places in realizing their fees.

North-Western Provinces and Oudh.

The steady progress in vaccination which had characterized the North-Western Provinces in previous years was arrested in 1897–98. This was due chiefly to the low birth-rate of the year. There were besides other special difficulties: many of the children in the famine-affected districts were in too reduced a condition to undergo the operation, and the time of the officers of the Vaccination Department was much occupied with plague duties. The results of 1898–99 were more satisfactory. The total number of persons vaccinated rose from 1,385,005 in 1897–98 to 1,398,684 in 1898–99, and the successfully vaccinated from 1,224,603 to 1,269,493. The proportion of persons protected by vaccination is still very small, the ratio for the year being only 26·92 per 1,000. Primary vaccinations numbered 1,340,036, of which 94·96 per cent. were successful. Of the 1,269,493 successful primary cases, 637,472 were infants and 483,106 were children over one and under six years of age. Estimating the births at 40 per 1,000 of the population, 33·80 per cent. were successfully vaccinated during the year.

Since the 1st February 1896 the areas of operation have been rearranged in two circles for the purposes of control, each being in charge of a Commissioned Medical Officer, acting as Superintendent of Vaccination and Deputy Sanitary Commissioner. In the first circle, the average ratio of success of its 27 districts equalled 27·60 per 1,000 of the population. In the second circle, the average ratio of its 22 districts was 26·33. The Vaccination Act is in force in all the municipalities, but the thoroughness of enforcement is said to vary considerably. In the municipalities there was an increase of 2,672 in successful primary vaccinations, and the proportion of persons successfully vaccinated per 1,000 of population rose from 32·51 per 1,000 in 1897 to 33·11 in 1898.

Punjab.

There was a further falling of in the number of vaccinations in the Punjab, as compared with the preceding year. Altogether 840,868 operations were performed in 1898–99, showing a decrease of 4,623 on the figures of 1897–98. Various reasons were assigned for the decline in the work; but these not being considered satisfactory, the Local Government asked for further explanation. The decrease, however, was entirely under secondary operations, as the primary vaccinations rose from 631,774 in the previous year to 661,937, of which 94·84 per cent. were successful. The Sanitary Commissioner hoped that there would be a greater increase in 1899, and that there would be an improvement in re-vaccinations. "The importance of re-vaccination," he writes, "is often forgotten. Primary vaccination protects infants and young children, but leaves the older generation unprotected or only partially protected." The number of successful cases among children under one year of age rose from 476,723 or 57·5 per cent. of the births, calculated at 40 per 1,000 of population, to 493,085 or 59·9 per cent. The provincial ratio of persons successfully vaccinated per 1,000 of the total population was 35·41, against 35·04 in the previous year. During the year the Vaccination Act was extended to the municipal town of Gujranwala, and at the end of the year it was in force in 19 towns.

Burma.

Satisfactory progress was made in vaccination work in the province of Burma during 1898-99. The total number of persons vaccinated was 480,657, as compared with 431,550 in the previous year. Out of 447,858 primary cases, 94·77 per cent. were successful, a ratio identically the same as in the previous year. The number of infants protected was 122,895, equal to about 38 per cent. of the births, estimated at 40 per 1,000 of the population. The returns for the Rangoon municipality were still far from satisfactory. There was again a decrease in the number of primary vaccinations, but a large increase in the number of re-vaccinations. The Vaccination Act is now in force in all the municipalities of the province. The attitude of the people towards vaccination is, the Superintendent General says, not by any means conciliatory, especially in rural areas, and much remains to be done before they get over their prejudices and take kindly to the operation.

Central Provinces.

Vaccination work in the Central Provinces was considerably hampered during 1897–98 by the famine. A return to more prosperous times, a higher birth-rate, and lower infantile mortality, was followed by satisfactory improvement in the work of the department. There were 449,250 persons vaccinated during 1898–99, showing an increase of 50,551 on the number of the previous year. Primary vaccinations rose from 347,210 to 383,633. The percentage of success in primary cases was 96·82, against 96·67, and the proportion of the total population protected by vaccination was 31·70 per 1,000, as compared

with 28·39 in 1897–98. Of the 18 districts in the province, only four showed a decrease in primary operations, against 12 in the previous year. In the protection of infants there was an increase of 42,783, the number vaccinated under one year of age during the year having risen from 187,437 to 230,220. Animal lymph supplied the bulk of the vaccination, and worked very successfully, and there is now very little prejudice against its use in the province. Arm-to-arm vaccination is now practised in very few places. With the lymph obtained from calves, 270,737 children were vaccinated during the year, and of these 254,561 were successful.

Assam.

There was a considerable falling off in vaccination work in Assam during 1898–99, particularly in the districts of Sibsagar and Nowgong. There were 258,905 operations performed by all agencies in the province ; which is a decrease of 25,009 on the figures of 1897–98. There was, however, an improvement in several of the districts, especially in Kamrup and the Garo Hills, where the operations were greater by 7,909 and 7,068 respectively. The largest decrease occurred in Sibsagar district (12,644), followed by Nowgong (10,312). Of the total operations 237,008 were primary cases, and of these 98·35 per cent. were reported as successful. The Compulsory Vaccination Act was in force during the year in the same 11 towns as in the previous year, their population being 71,128. The number of infants successfully vaccinated was 50,389, representing only 22·36 per cent. of the births, estimated at 40 per 1,000 of the population, and the proportion of the population successfully vaccinated was 40·58 per 1,000. Arm-to-arm vaccination has now been practically abandoned throughout the province, and no operations of this class were reported during the year.

Madras.

The total number of vaccinations performed in the Madras Presidency during 1898–99 was 1,117,993, being a decrease of 153,736 on the operations of the previous year, the falling off being mainly attributable to a confusion by the people of vaccination with plague inoculation. Of the total, 1,039,713 were primary cases, of which 89·5 per cent. were successful, against 92·0 per cent. in 1897–98. The number of children under one year of age successfully vaccinated fell from 331,297 to 282,969, which represented only 19·84 per cent. of the estimated births, being 3·4 below the percentage of the previous year. Vaccination is compulsory in all municipalities, and the number of operations performed by municipal vaccinators rose from 118,655 to 127,724. In the town of Madras the number of operations performed was 28,186, a decrease of 4,896 on the previous year, which was chiefly due to a diminution in the number of unprotected children in consequence of a decrease in the number of births. Of the 21 districts, all but three (Ganjam, Vizagapatam, and Godavari) recorded a decrease of work, the most marked cases being those of Salem (28,501), South Arcot (23,993), and North Arcot (23,844). The increase in Vizagapatam was satisfactory, as the heaviest fall occurred in this district in the previous year. The operations were performed solely with animal lymph, and the best results were obtained, as usual, from calf-to-arm vaccination, with a percentage of success of 97·2 against 97·5 in the previous year.

Bombay.

The plague epidemic again seriously interfered with vaccination work in Bombay Presidency. The work was also affected by the absence of inspectors and vaccinators on plague duty, by the very low birth-rate of the two previous years, and high death-rate of 1897, and by the movements of the people in parts on account of scarcity and plague. Omitting the statistics of five Native States which are not under the supervision of the Vaccination Department, the out-turn of vaccination work in the Presidency fell from 744,650 operations in 1897–98 to 674,950. The total primary cases fell from 681,289 to 623,796 ; the percentages of success being respectively 91·84 and 92·84. The substitution of animal for human lymph continued to increase in the Presidency. In the City of Bombay vaccination with animal lymph has been in use for many years past. Of the 579,144 primary successful cases, nearly 78 per cent. were infants under one year of age. Reckoning the births at 40 per 1,000 of population, about 50 per cent. were protected from small-pox. Inoculation was not practised anywhere in the Presidency during the year, and no instances were reported of any disease having been communicated through vaccination.

Berar.

Vaccination work continues to make satisfactory progress in Berar. During 1898–99, 132,903 operations were performed, against 125,289 in 1897–98. The increase, however, was again entirely under revaccinations, as the primary vaccinations fell from 95,048 to 94,032 ; while the percentage of success rose from 96·4 to 97·1. Of the total number of successful primary operations, 69,887 were performed on infants under one year of age ; estimating the births at 40 per 1,000 of population, 60·3 per cent. were protected from small-pox. The decrease in primary vaccinations was confined to the three districts of

Amraoti, Ellichpur, and Wun, but in the remaining three districts the increase was not very great. In revaccinations there was an increase of 8,630, which was spread over all the districts except Buldana. The Sanitary Commissioner continues his statement showing the efficacy of vaccination in checking small-pox mortality in Berar ; the ratio of successful vaccinations per 1,000 of population has risen from 8·92, the mean of five years 1868–69 to 1872–73, to 33·6, the mean of five years ending 1897–98 ; the mortality from small-pox for the same periods has declined from 2·02 to 0·19 per 1,000. In 1898–99 the ratio of successful vaccinations per 1,000 of population was 34·6, and the death-rate from small-pox 0·2 per 1,000. The Vaccination Act is now in force in all the municipal towns.

VI.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

The following comparative statement shows the number of hospitals and dispensaries open in the several provinces of India during 1898 and the previous year, and the number of patients under treatment :—

Provinces, &c.		Number of Institutions.	Number of In-door Patients.	Number of Out-door Patients.	Total Number of Patients.
Bengal	1898	487	42,086	2,837,759	2,879,845
	1897	477	55,644	2,778,468	2,834,112
Calcutta and Howrah	1898	15	23,732	187,518	211,250
	1897	16	28,955	260,806	289,761
North-Western Provinces and Oudh	1898	369	55,589	3,801,255	3,856,844
	1897	355	56,936	3,635,480	3,692,416
Punjab	1898	267	49,068	2,976,321	3,025,389
	1897	265	52,381	3,241,543	3,293,924
Burma	1898	105	34,091	765,430	799,521
	1897	99	34,102	754,458	788,560
Central Provinces	1898	125	11,179	1,536,739	1,547,918
	1897	121	14,170	1,512,489	1,526,659
Assam	1898	108	6,977	603,290	610,267
	1897	101	7,222	602,268	609,490
Coorg	1898	7	1,381	40,015	41,396
	1897	7	1,832	49,970	51,802
Madras	1898	486	60,244	4,209,331	4,269,575
	1897	480	63,130	4,247,138	4,310,268
Bombay	1898	325	46,468	1,787,787	1,834,255
	1897	323	47,763	1,766,783	1,814,546
Berar	1898	47	3,460	301,527	304,987
	1897	47	6,789	318,977	325,766
TOTAL	1898	2,341	334,275	19,046,972	19,381,247
	1897	2,291	368,924	19,168,380	19,537,304

Bengal. There was a further increase in the number of charitable dispensaries in Bengal in 1898, and in the patients under treatment in them, as compared with the figures of the previous year. The total number of dispensaries at work during 1898 in Bengal, exclusive of the medical institutions at Calcutta, was 487, an increase of 10 on the number of the preceding year. At these there were 2,879,845 patients under treatment, 42,086 being in-door and 2,837,759 out-door patients, against 55,644 and 2,778,468 respectively in the previous year. This shows a total increase of 45,733, which was entirely in out-door patients, as the in-door patients decreased by 13,558. The increase in the number of out-door patients is considered particularly satisfactory, "inasmuch as it occurred in an exceptionally healthy year, and one in which the fear of plague measures might have been expected to deter the people from having recourse to Government dispensaries."

There was again a satisfactory increase in the number both of women and children patients. The increase among women amounted to 3,742, the number having risen from 458,670 to 462,412. The proportion of women was, however, slightly lower than in the previous year, "owing to the credence given to rumours that Government plague measures in some way affected the honour and safety of women." Of the diseases

under treatment at the dispensaries, malarial fevers, skin diseases, and dysentery and diarrhœa were responsible, as usual, for the largest number of cases. From malarial fever there were 527,695 cases, equal to nearly 18½ per cent. of the total number of patients, against 536,428 in 1897; from skin diseases the number of cases rose from 379,437 to 402,890; from dysentery and diarrhœa there were 154,117 cases, against 166,516 in 1896; and from cholera the number of patients fell from 16,845 to 6,425. Cases of venereal diseases rose from 72,507 to 77,603. The number of deaths among in-door patients fell from 8,172 or 146·8 per 1,000 of total treated in 1897 to 4,718 or 112·0 in 1898. Great attention is paid in these institutions to surgery, and during the year 137,123 operations were performed, against 135,507 in 1897, and of these 180 terminated fatally. Among the more important operations there were 2,259 cases of extraction of the lens.

The following statement shows the number of in-door and out-door patients treated in the several hospitals and dispensaries in Calcutta and Howrah during 1898 and the previous year :—

Name of Institution.	1898.				1897.			
	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.
Medical College Hospital	4,667	28,386	33,053	109·2	4,672	36,424	41,096	121·5
Eden Hospital	1,413	3,423	14,836	77·1	1,595	3,811	5,406	78·3

Total Calcutta Hospitals and Dispensaries	22,270	176,878	199,148	123·8	27,180	248,972	276,152	153·3
Howrah General Hospital	1,462	10,640	12,102	207·9	1,775	11,834	13,609	277·1
Grand Total	23,732	187,518	211,250	129·0	28,955	260,806	289,761	160·9

The figures for 1897 show a decrease of 73,288 in out-door patients, and of 5,223 in in-door patients. The death-rate for all the hospitals was 129·0 per 1,000 of the total in-patients, against 160·9 in the previous year. Cholera patients fell from 1,200 to 227, and the fatal cases from 664 to 122. The decrease was most marked in the Campbell Hospital, where only 89 cases were treated against 535 in the previous year. Small-pox was less prevalent in Calcutta than in the previous year, and the cases admitted to hospital declined from 218 to 37. Dysentery was less prevalent, and the number of patients fell from 8,415 to 5,571. The number of patients treated for diarrhœa was also less, viz., 6,244 against 9,836; malarial fever was responsible for 37,276 patients against 46,025. Venereal diseases show a decrease of 3,592 patients, the number treated having fallen from 14,523 in the previous year to 10,931. Surgical operations decreased from 25,745 to 21,610, and death ensued in 154 cases, against 178 in 1897.

North-Western Provinces and Oudh.

During 1898 there were 369 hospitals and dispensaries at work in the North-Western Provinces and Oudh, or 14 more than in the previous year. The number of patients who received medical aid was 3,856,844, against 3,692,416 in 1897. There was thus an increase in 1898 of 164,428, which was entirely among out-patients, as the in-patients declined from 56,936 to 55,589. The figures, however, indicate a return to normal conditions, as there had been a falling off in 1897, "owing to the fears excited by plague preventive measures, and to the fact that many people who might otherwise have come to dispensaries flocked to famine poor-houses and relief works." Of the total number, 52·5 per

cent. were men, 22·6 per cent. were women, and 24·8 per cent. were children, the two latter showing a small increase on the figures of the previous year, which were 22·4 and 24·2 respectively. Among the in-door patients there were 2,801 deaths, giving a death-rate of 50·3 per 1,000, against 4,514 or 79·2 in the previous year. Of the diseases for which the patients were treated 692,233 were suffering from malarial fevers, a decrease of 20,789 on the number of 1897 ; cases of cholera fell from 3,585 to 368, and cases of diseases of the eye rose from 302,319 to 318,522. From venereal diseases there were 95,165 patients, against 89,012 in the previous year. The number of surgical cases rose from 168,538 to 175,708, of which 142,629 resulted in cure and 366 were fatal. Of the total operations 5,648 were for cataract, of which nearly 83 per cent. were successful, as compared with 6,566 operations and a percentage of success of 81 in 1897.

Punjab.

The number of dispensaries at work in the Punjab during 1898 was 267 or two more than in the previous year. At these, 3,025,389 patients were under treatment, being a decrease of 268,535 on the number of 1897. The attendance of in-door patients was less than in the previous year by 3,313, the number having fallen from 52,381 to 49,068. The decrease was attributed partly to greater care being taken about the class of patients admitted so as not to convert the hospital into a poor-house, and partly to several dispensaries having to be closed on account of the staff and many civil surgeons being taken away for plague duty ; the latter cause, and a more healthy year, contributed greatly to the decrease in out-patients. Of the diseases for which patients sought relief there were only three cases of cholera, being a decrease of 95 on 1897. Cases of malarial fever fell from 646,471 to 463,223. Diseases of the eye showed a decrease of 633 cases, the number treated in 1898 being 381,408, against 382,041. From venereal diseases there were 28,659 cases under treatment, a decrease of 2,260 on the previous year's figures. Among the in-patients there were 2,061 deaths during the year, being in the ratio of 42·0 per 1,000 of the number treated, against a death-rate of 47·5 in 1897. In surgical work the operations decreased from 173,808 in 1897 to 170,809. Of these, 164,164 were cured and 278 died. There were 4,534 cataract operations, and of these 87·5 per cent. resulted in cure.

Burma

The number of dispensaries existing in Burma at the end of 1898 was 105, or six more than in the previous year. At these, 799,521 patients attended, as compared with 788,560 in 1897. In-door patients were slightly fewer, the number having declined from 34,102 to 34,091, of whom 24,860 were cured, and 2,487 or 73 per 1,000 died, against 2,613 deaths or 80 per 1,000 in the previous year. Nearly three-fifths of the patients treated were Burmese. Malarial fevers, as usual, headed the list of maladies under treatment, the number of cases being 127,177, against 130,180 in the previous year. Cholera was less prevalent than in 1897, and the number of cases fell from 914 to 342, of which the majority were in the lower part of the province. Cases of venereal disease rose from 27,164 in 1897 to 28,966. Surgical work showed a decrease of 1,224 operations, the number performed during the year having fallen from 17,714 to 16,490 ; the falling off was due to the smaller number of abscesses being opened, and to the comparative healthiness of the year. The number of patients cured, after being subject to operation, was 15,684, and 85 died.

Central Provinces.

The number of hospitals and dispensaries at work in the Central Provinces during 1898 was 125, or 4 more than in the previous year. The total number of patients rose from 1,526,659 to 1,547,918. The increase, however, extended only to out-door patients, the in-door patients having fallen from 14,170 to 11,179. Among the in-patients there were 1,042 deaths or 93·2 per 1,000 of total treated, against 1,905 or 134·4 in 1897. As regards the different kinds of diseases, the most remarkable features were the large decrease of cases of malarial fevers by 17,533, against an increase of 47,713 in the previous year, a fact which points to the healthy character of the year, and of 32,063 cases of dysentery and diarrhœa. From venereal diseases there was an increase of 2,596 cases. There were 39,552 surgical operations performed, against 35,102 in 1897. Of these, 37,176 resulted in cure and 65 in death. In the four years ending 1896 there had been a considerable increase in operations for cataract, viz., from 479 in 1893 to 1,508 in 1896 ; in 1897 they fell to 964, but rose again in 1898 to 1,026.

Assam.

In the province of Assam there were 108 dispensaries at work during the year, or seven more than in the previous year. Notwithstanding the healthiness of the year the number of patients was greater than in 1897, "a gratifying sign that the advantages offered by dispensaries are becoming more appreciated." The total number of patients treated was 610,267, against 609,490 in 1897. The in-patients declined from 7,222 to 6,977, and of these 3,955 were discharged cured, 512 relieved,

1,111 discharged otherwise, and 1,121 died, the latter representing 160·7 per 1,000 of the total in-patients, against a ratio of 209·4 in 1897. The number of natives of the country treated as in-patients rose from 1,772 in 1897 to 1,844, but the number of foreigners fell from 5,450 to 5,133, mostly *ex*-tea-garden and *ex*-railway coolies, many of them being admitted in a moribund condition, which partly accounts for the high mortality in the dispensaries during the year. Of the total number of persons who received medical aid, malarial fever accounted for 177,470 cases, including 5,572 suffering from kala-azar; skin diseases other than ulcers 104,598, worms 81,756, dysentery and diarrhœa 32,874, and diseases of the digestive system 28,776. Cholera patients numbered 2,972, against 3,026 in 1897. More than half (1,621) were under treatment in the Manipur dispensary, an unprecedented epidemic of cholera having occurred in Manipur during the year. Of surgical cases there were 14,701, of which 14,004 were cured and 32 were fatal.

Madras. Exclusive of the hospitals in the Presidency town there were 472 civil hospitals and dispensaries working in Madras at the close of 1898, or six more than in 1897. There were 4,067,111 patients under treatment, as compared with 4,092,551 in 1897. There was thus a decrease of 25,440. Of the 41,660 in-door patients, 25,298 were returned as having recovered fully under treatment, 8,824 as relieved, and 3,023 as otherwise discharged. The deaths numbered 2,963, representing a ratio of 71·1 per 1,000 of the total in-patients, against 80·4 in the previous year. Ulcers and diseases of the skin, diseases of the eye, diseases of the digestive system, malarial fevers, rheumatic affections, dysentery, and worms were the most common diseases under treatment during the year. Cholera was much less prevalent in the Presidency than in the previous year, and the cases under treatment in the various hospitals and dispensaries fell from 23,500 to 9,783. From venereal diseases there were 83,328 cases, against 79,570 in 1897. The surgical operations fell from 150,766 in 1897 to 147,001. Of these, 136,295 were cured and 216 terminated fatally.

The number of medical institutions in Madras town remained the same as in 1897, but the number of sick treated declined from 217,717 to 202,464. The in-patients fell from 18,908 to 18,584, and amongst them 9,142 cases were recorded to have been cured or perfectly recovered, 4,040 were relieved, 3,041 discharged otherwise, and 1,494 or 80·2 per 1,000 died, against a rate of mortality in 1897 of 60·5. The high mortality was due to the general unhealthiness of the year, and to the aggravated forms of disease treated. Of the several diseases for which the patients were treated, malarial fever, diseases of the digestive system, skin, and respiratory system were, as usual, the most common. From cholera there were 505 cases, from dysentery and diarrhœa 7,344, and from venereal diseases 4,523. The surgical operations performed in 1898 decreased from 31,794 to 28,725. The results showed that 13,739 cases were cured, 3,791 relieved, and 137 were fatal.

At the Madras Voluntary Venereal Hospital, which is included in the above hospitals in the city, there were 638 female patients treated during 1898, an increase of 80 on the number of the previous year.

Bombay. Excluding the 11 medical institutions in the City of Bombay, there were 314 hospitals and dispensaries working in the Presidency at the end of 1898. At these, 1,751,236 patients were under treatment, of whom 29,904 were in-door and 1,721,332 out-door patients, against 32,585 and 1,710,219 respectively in 1897. There was thus an increase of 8,432, all being out-patients. As in the previous year, the prevalence of plague had an important indirect effect on the mofussil hospitals and dispensaries in diminishing the attendance of patients, certain institutions having to be temporarily closed owing to the withdrawal of their hospital assistants for plague duty. Malarial fevers, as usual, constituted by far the largest number of cases (302,105), an increase of 20,464 on the figures of the previous year. Next to fever, eye and skin diseases and worms were the most common ailments. Small-pox cases were slightly less numerous, the number having fallen from 495 in 1897 to 438; cholera cases fell from 5,741 to 606; dysentery cases were also less numerous; while patients suffering from venereal affections rose from 24,580 in 1897 to 27,217 in 1898. Of the in-door patients 21,834 were cured, 1,917 relieved, 1,891 discharged otherwise, and 3,071 died, the ratio of deaths to total treated being 103 per 1,000, against 146 in the preceding year. The total number of patients operated on was 83,255, as compared with 82,564 in 1897, and of these 68,915 were cured and 190 died.

The total number of patients treated at the 11 civil medical institutions working in the town of Bombay during 1898 showed an increase of 11,277, the figures being 83,019, against 71,742 in the previous year. The in-patients increased in number from 15,178

to 16,564, and of these 10,144 were cured, 2,518 relieved, 883 otherwise discharged, and 2,063 died, the deaths being in the ratio of 125 per 1,000 of the in-patients, against 136 per 1,000 in 1897. As usual, local injuries, malarial fevers, eye diseases, and skin diseases were responsible for the majority of the cases. Venereal diseases contributed 3,771 cases, against 4,445. There were no cases of cholera under treatment; those of dysentery fell from 1,384 to 1,040; while diarrhœa cases rose from 2,795 to 2,830. The total number of patients operated on was 18,399, and of these 12,368 were cured, 243 relieved, 54 discharged otherwise, and 163 died.

Berar.

There were 47 medical institutions at work in Berar during 1898, the same as in the previous year. Of these, eight are hospitals wholly maintained by the State. The total number of patients under treatment was 304,987, against 325,766 in 1897. In in-patients there was a decrease of 3,329, and in out-door patients of 17,450. The Inspector General says: "There was no famine in the year under report to fill our charities with in-"patients as in the previous year, and the year itself was comparatively a healthier one "as gauged by the death-rate per mille of the population of the province for the two "years 1897 and 1898, which was 52·6 and 23·4 respectively. These two favourable "features would account for the general fall in attendance during the year." Of the in-patients, 2,894 were cured and 193 died, which gives a death-rate of 56 per 1,000, as compared with a mortality of 923 or 136 per 1,000 in 1897. Malarial fevers continued to head the list of diseases from which relief was sought, but the cases again fell from 66,566 in 1897 to 66,288; nearly a fifth of the total patients were treated under this head; diseases of the eye and diseases of the digestive system came next in order. The number of surgical operations was 10,606, against 9,944 in 1897. Of these, 10,368 were cured and 22 died.

Attendance at the Secunderabad Civil Hospital, not included in the above total, showed an improvement, the number of in-patients having risen from 603 in 1897 to 608, and out-door patients from 19,024 to 19,784. The surgical operations rose from 618 to 898.

The Dufferin Hospital for women and children at Amraoti, which was opened on the 15th February 1895, showed a decline in work as compared with that of the previous year. The in-door patients during 1898 numbered only 143, against 257 in the previous year, and the number of out-door patients (5,913) remained the same.

Lunatic Asylums.

Bengal.

At the five asylums in Bengal (viz., Dullunda, Dacca, Patna, Cuttack, and Berhampore) 1,083 lunatics, including 159 fresh admissions and re-admissions, were under treatment in 1898, being a decrease of 36 on the number of the previous year. In the course of the year under notice 71 patients were discharged as cured, and 28 as improved or otherwise, and 73 died. Compared with the figures of 1897, the number discharged was less by 14, and the mortality by 17. At the end of the year there were 911 persons still under detention, or 12 less than at the close of 1897. There was a marked improvement in the health of the inmates of the asylum, the average daily number of sick being 105, against 129, and the death-rate (79·1 per 1,000 of average strength) was the lowest on record during the last 13 years, except 1890, and nearly 20 per 1,000 below 1897. The cause of insanity was traceable only in 61 of the 159 fresh admissions, 21 of these being ascribed to ganja. The results of the working of dairy farms at the asylums were satisfactory. At Dullunda there was a profit of Rs. 641 as compared with a loss of Rs. 1,134 in the previous year, when "a number of dry cows had to be fed until they "were disposed of, and in a year of scarcity the cost of up-keep of such cows was very "high." At Dacca the dairy showed a small profit of Rs. 37. The dairy farm at Berhampore, which was opened in the latter part of 1896, also worked with better results.

In the Bhowanipur Asylum, containing European and Eurasian patients only, the inmates during 1898 numbered 53, against 55 in the previous year. Of this number 35 were under detention at the beginning of the year, and 18 were subsequently admitted. In the course of the year 4 patients were discharged cured, 9 were transferred to the care of friends, and 2 died, leaving 35 under confinement at the close of the year. As regards the health of the patients during the year, there were only 5 admissions to hospital, and 2 deaths.

North-Western Provinces and Oudh.

The inmates of the four lunatic asylums (Agra, Bareilly, Benares, and Lucknow) in the North-Western Provinces and Oudh in 1898 numbered 1,290, including 206 fresh admissions during the year, against 1,334 in 1897. Before the close of the year 173 patients were discharged, of whom 134 were reported as cured, 39 were made over to friends, and 87

died, leaving 1,030 under treatment at the end of the year. The health of the asylum population showed no improvement, and the 87 deaths which occurred yielded a somewhat higher death-rate on the reduced population, viz., 82·6 per 1,000 of average strength, against 78·4 in 1897. The scheme for a large central institution at Agra, under the charge of a whole-time Superintendent, was still under consideration at the close of the year. It is stated, however, that "administrative sanction to the project at an estimated cost of about £21,000 has been accorded, and definite proposals about the staff are now being matured."

Punjab. The total number of lunatics in the Lahore and Delhi lunatic asylums in the Punjab during 1898 was 558, including 170 fresh admissions, against 526 in 1897. These figures are the highest on record, but the increase is thought to be due to greater readiness on the part of magistrates to grant admission orders, and to greater willingness on the part of friends to place patients under restraint, and not to any general increase of insanity in the province. At the end of the year the number was reduced to 424 by the discharge of 94 patients (55 as cured, 24 made over to friends, and 15 otherwise discharged) and 40 deaths. In both asylums there was less sickness among the inmates than in the previous year, but the mortality was much higher. The total number of hospital cases was 470. In Lahore the cases fell from 498 in 1897 to 423, and the deaths rose from 21 or 81·5 per 1,000 of daily average strength to 26 or 90·8 In the Delhi Asylum the deaths numbered 14 or 107·1 per 1,000, against 11 or 85·8 in 1897. No special diseases were present in any unusual degree, except pneumonia at Lahore, the cases having risen from 3 to 21. Unusual cold is supposed to have been the cause of this increase, as almost all the other circumstances were identical in both years. In the Delhi Asylum, on the other hand, pneumonia cases fell from 10 to 4.

Burma. The Rangoon Asylum is the only one in the province of Burma. Until the year 1894 a number of lunatics were, for want of accommodation, confined and treated in the Rangoon central jail. The asylum has since been twice extended, and there is now accommodation for 404 insanes. During 1898 there were 430 patients in the Rangoon Asylum, including 88 fresh admissions, and the total was reduced at the close of the year to 345 by the discharge of 44 patients for different causes, and the death of 41. The daily average sick was higher than in 1897, and the admissions to hospital rose from 139 to 173. No epidemic disease occurred among the patients, but the deaths rose from 36 or 108·0 per 1,000 of average strength to 41 or 119·2. More than half (22) of the inmates who died were in bad or indifferent health at the time of admission to the asylum. Of the 430 insanes 196 were criminal lunatics, and among them were 12 deaths, equal to 61·2 per 1,000 of average strength, as compared with 29 or 123·9 among civil lunatics, the high mortality among the latter being attributed to their general bad state of health on admission, some having died a few days after admission, and 13 within less than six months.

Central Provinces. In the two asylums of the Central Provinces (Nagpur and Jubbulpore), there were 384 lunatics under treatment during 1898, an increase of two on the number in 1897. In the course of the year 34 patients were discharged as cured or otherwise, and 24 died, leaving 326 still under treatment at the end of the year. The admissions to hospital at Nagpur rose from 59 to 205, but at Jubbulpore they fell from 108 to 100. The chief causes of sickness were influenza of a mild form (which was confined to the Nagpur Asylum, causing 129 admissions), fevers, dysentery, debility, and bronchitis. Of the total 24 deaths, Nagpur recorded 17, being in the ratio of 104·6 per 1,000 of average strength, against 14 or 83·7 in 1897. Nine of the 17 deaths in this asylum were due to dysentery and debility. At Jubbulpore there were 7 deaths, being in the ratio of 45·8 per 1,000, against 13 or 86·2 in 1897.

Assam. There is only one lunatic asylum in the province of Assam. This is situated in Tezpur, and the building is reported to be at present large enough for all demands on it. The total number of lunatics under treatment in the asylum during 1898 was 147, or six less than in the previous year. Of these, 29 were fresh admissions. At the close of the year the patients in the asylum were reduced to 125, 17 of the total number having been discharged, and 5 died. The health of the inmates was very satisfactory, being partly due to the salubrity of the year in the district; and the mortality was lower. Among the 147 inmates 86 were admitted to hospital, as compared with 92 in 1897. The number of deaths was less by five than in 1897, and the death-rate fell from 81·6 per 1,000 of average strength to 40·3.

Madras. At the commencement of 1898 there were 580 patients under treatment in the three lunatic asylums (Madras, Vizagapatam, and Calicut) of the Madras Presidency. During

the year 134 fresh cases were admitted, bringing the total population up to 714, or 28 less than the number in the preceding year. In the course of 1898 there were 91 cases of discharge, and of these 75 were cured or improved. The accommodation was ample, and there was no overcrowding in any of the asylums during the year. On the whole there was less sickness among the patients than in the previous year; the daily average sick fell from 78 to 75, and the deaths from 59 or 100·5 per 1,000 of average daily strength, to 46 or 79·3. Beyond an outbreak of chicken-pox in the Madras Asylum, from which there were no deaths, all three asylums were free from epidemics. Of the total 46 deaths the Madras Asylum contributed 32, giving a death-rate of 75·2 per 1,000 on an average strength of 426, against a ratio of 87·8 in 1897. The death-rates of the other two asylums, Vizagapatam and Calicut, were 82·7 and 97·2 per 1,000 respectively, against 14·0 and 223·4 in the previous year. The increase in the mortality in the Vizagapatam Asylum was due to unavoidable causes. Of the six deaths in this asylum two were cases of chronic mania, and two others were paralytic.

Bombay

The total population of the six lunatic asylums of the Bombay Presidency (Colaba, Ratnagiri, Poona, Dharwar, Ahmedabad, and Sir Cowasji Jehangir, Hyderabad) was 1,043, including 282 fresh admissions, against 1,029 in 1897. In the course of the year 175 patients were discharged, 80 of them as cured, and 55 died, leaving 811 under treatment at the close of the year. There was slightly less sickness in the asylums than in 1897, the daily average sick having decreased from 49 to 41, the deaths also fell from 81 or 105·9 per 1,000 of average strength, to 55 or 69·9. Of the 55 deaths, 9 were due to dysentery, 8 to phthisis, 7 to diarrhœa, 4 each to debility and Bright's disease, and 5 to anæmia. The death-rate was lower in all the asylums. The Poona Asylum recorded the highest mortality, viz., 70·4, but this was nearly 15 per 1,000 lower than the ratio of 1897.

Medical Schools.

Bengal.

The number of medical schools open in Bengal during 1898–99 was 11. The Medical College, Calcutta, and four of the medical schools are maintained by Government, the rest are unaided—two being schools of homœopathy. The college is affiliated to the University, and prepares candidates for its various medical degrees. The four Government medical schools train pupils as Civil Hospital Assistants, and the six unaided schools follow their own standards for private practice. The total number of pupils attending the various medical schools in the province was 1,709, as compared with 1,815 in the previous year.

The number of students at the Calcutta Medical College at the beginning of the session in 1898–99 was 576 (including 14 women), against 583 in the preceding year. As regards the examinations, 217 candidates were successful out of a total of 445 (including 4 women), the successes being at the rate of 49 per cent., as compared with 44 per cent. in 1897–98. Of the 217 successful candidates, 37 (including one woman) passed the Preliminary Scientific L.M.S. examination, 90 passed the first, and 51 (including two women) the second L.M.S. examinations; 25 passed the Preliminary Scientific M.B. examination; nine passed the first and three the second M.B. examinations; seven native dais passed in midwifery from the Eden Hospital, and received certificates of qualification, and 17 pupil nurses also passed as midwives.

The Campbell Medical School had 202 pupils (including 17 women) on its rolls at the end of the session. Of this number 27 males and 3 women passed the final examination for the diploma.

At the Dacca Medical School there were 144 pupils on the rolls (including 8 women). Fourteen students passed the final examination.

The Temple Medical School, Patna, had 115 students (including 2 women) on its rolls at the end of the session. At the final examination 3 candidates passed.

At the Cuttack Medical School the number of pupils at the close of the session was 104 (including six women). All the 13 candidates that appeared at the final examination passed.

North-Western Provinces and Oudh

The number of pupils attending the Agra Medical School in 1898–99 was 258 (including 63 women), or one more than in the preceding year. The results of the final examination of male students show that 45 out of 65 candidates passed. Eleven of the 15 military students in this class passed, and 29 of the 41 civil students passed. Of the students in Class II., comprising second-year military and third-year civil, private, and Rajputana pupils, 9 out of 12 military pupils and 21 out of 24 civil pupils passed the first half professional examination.

As regards women students, the examination results show a slight falling off. Six obtained their diplomas ; 7 out of 11 students in Class I. passed the final examination, and 9 out of 11 in Class II. or third year students were promoted.

Punjab. The average attendance at the Lahore Medical College and School was somewhat larger than in 1897–98, viz., 443 against 415. Of these 212 (including 8 women) were in the College, and 231 (including 3 women) in the Medical School. It was thought that the introduction of a higher qualification in general education as a condition of admission would have been the means of decreasing the number of college students, as in the previous year there was a falling off of 37 ; the effect, however, was only temporary, as the attendance rose from 210 to 212. The results of the year's examinations show that for the Preliminary Scientific Examination, held for the first time, 18 out of 20 candidates passed. In the first L.M.S. and M.B. examinations, 32 candidates out of 66 passed against 22 out of 66 in the previous year, and in the second L.M.S. and M.B. examinations 21 out of 52 passed against 16 out of 37.

In 1894 a medical school for women, called the North India Medical School for Christian Women, was opened at Ludhiana. The object of the institution is " to provide a thorough " medical training, under fully qualified Christian women, for those Christian women and " girls who wish to prepare themselves for medical mission work." At the end of 1898 there were 26 students on the rolls, or 6 more than in the previous year, and they were reported to be making satisfactory progress. Besides these 12 others were under training as dais. The students were this year recognised as eligible for admission to the examination for Hospital Assistants.

Madras. The number of students at the Madras Medical College (including the School Department) during 1898–99 was 456, including 35 women students. In the Hospital Assistant Department, consisting of 190 pupils, 68 appeared for the final examination, of whom 55 passed. The results of the several University examinations were again satisfactory, 26 having passed out of 57 candidates entered, against 32 out of 63. In the College Department there were, as in the previous year, 53 regular students reading for the M.B. and C.M. degree, 12 reading for the L.M.S. degree, and 17 casual students.

The Board Medical School at Nellore having been closed, the only other medical school at work during the year was the Prince of Wales' Medical School, Tanjore. At this there were 50 pupils on the rolls, all of whom were being prepared for the Hospital Assistants' Certificate. Twenty-one candidates appeared for the final examination and 14 passed.

Bombay. The attendance at the Grant Medical College, Bombay, rose from 320 in 1897–98 to 340 (including 24 women) in 1898–99. For the first University examination in medicine 130 candidates presented themselves, of whom 52 qualified ; and for the second examination in medicine 27 passed out of 69 candidates. For the final examination for the degree of L.M.S there were 54 candidates, and of these 20 passed, 2 qualifying in the first and 18 in the second class. There were 29 military medical pupils, of whom several were engaged on plague duty during their regular course of study, and were therefore allowed to continue in the College for a further period of six months before final examination.

The Government Medical Schools at Poona, Ahmedabad, and Hyderabad continued to work satisfactorily. The number of students was 269, and the results of the examinations were satisfactory.

VII.—SANITATION.

In Calcutta progress continued to be made in the improvement of bustees, or clusters of Native huts. In the matter of water supply there is nothing to record but the ordinary progress of the existing system. The average daily consumption of filtered water was 20,684,000 gallons, equal to 34 gallons per head of population for the town proper, and 20 gallons for the suburban area. In the course of the year the distribution pipes were slightly extended, bringing the total length up to a little over 315 miles, and the total number of premises connected had reached 28,343. The consumption of unfiltered water was 4,779,000 gallons, or 12 per cent. less than in the previous year; the daily consumption per head of population was about 11 gallons. Extensive improvements in the sewage and storm water outfalls of the town and suburbs, and the provision of a system of sewers for the suburbs were in hand. At the close of the year (1898–99) the total length of public sewers was over 209¼ miles, and the number of premises connected with them was 30,168, of which 320 connections were made during the year. During the year the conservancy of the port of Calcutta was maintained in a good state. **Bengal.**

The total amount spent on sanitary works in the municipalities of the interior of Bengal was *£130,000, or 46 per cent. of their income, a decrease of £5,500 on the sum expended in the previous year. In addition, a further sum of £32,400 was contributed by private individuals for the same purpose, against £77,850 in the previous year. The most important works were the completion of a portion of the Champanagar and Nathnagar extension of the filtered water supply of Bhagalpur, the Berhampore water supply, and the extension of that of Cossipur-Chitpur. A drainage scheme for the latter municipality and one for Maniktola were under consideration, and the Krishnagar scheme had been adopted. The Howrah scheme, which was prepared by the engineer of the Calcutta Corporation, was found too expensive, and has fallen through.

The Sanitary Board were unable to hold more than one meeting during the year. They were, however, enabled by circulation of papers to undertake the usual consultative work. Among other important matters, they considered the water-supply projects in respect to Howrah (extension), Darjeeling, and other places, and drainage projects for Krishnagar, Monghyr, Comilla, Siwan, and elsewhere. The Board was specially engaged in discussing the Monghyr drainage scheme and the scheme for giving a water-supply to the municipalities on the right bank of the river Hooghly. The towns in which drainage schemes have been carried out numbered 16, exclusive of Calcutta, and nine towns have improved water-supply.

In the North-Western Provinces and Oudh, many sanitary improvements have been effected in the urban areas, especially in the large cities. The municipalities expended during 1898 nearly 40 per cent. of their income on water-supply, drainage, and conservancy. Eight towns, Agra, Allahabad, Benares, Cawnpore, Lucknow, Meerut, Mussoorie, and Naini Tal are now furnished with waterworks and pumping machinery, which give daily a quantity varying from 10¾ gallons per head of the population in Naini Tal, to 3½ gallons at Lucknow, and the reports of the Sanitary Board show that the quality of the water supplied is satisfactory. Progress was made with the Benares sewerage works, and a small amount was spent on sewerage at Mussoorie; the water-supply works at Allahabad were continued; at Naini Tal a water-supply scheme costing £17,000 was sanctioned in March, 1898, and the greater part of the work had been done by the end of the year. The comparative absence of epidemic disease, the extinction of plague, and the amelioration of the general health, combined with improvement in municipal sanitation, make the record of the year a satisfactory one. Orders were issued prescribing the maintenance of a village sanitation book in towns and villages for recording the need of local sanitation. **North-Western Provinces and Oudh.**

The Sanitary Board held three meetings during the year, when they made certain recommendations as to the examination of the water-supply of towns. Their attention was also directed to the insanitary condition of the town of Kosi, in Meerut district, owing to its high death-rate in the autumn of 1897. Improvements since effected are reported to have considerably reduced the mortality at Kosi.

In the Punjab the municipal towns spent nearly 25 per cent. of their income on sanitary work in the year 1898. Much was done to improve the sanitary state of many towns. Water-supply or drainage works were either completed, in progress, or under **Punjab.**

* Throughout this Report income and expenditure are shown in pounds, rupees being converted for the purpose at the rate of Rs. 15 = £1.

consideration in 15 of the most important towns. Of the water-supply works in progress the chief were two reservoirs at Simla, a water-supply for Haripur, which was completed, and preliminary work for a water-supply at Amritsar. Important works were under consideration in Bhiwani, Delhi, and Simla. The chief drainage works in progress were those at Delhi, Lahore, Mooltan, and Rawalpindi; projects were in course of preparation for Umballa, Jagraon, Ferozepore, and Fazilka. Some of these schemes are of considerable magnitude, the estimated cost of the Delhi drainage works now in progress being no less than £40,600; but no very large amount was spent during the year on any one project. Private individuals also spent sums aggregating £4,500 on the construction of minor sanitary works during the year 1898–99. The health statistics of the towns, as might be expected, show, with few exceptions, a marked improvement after the introduction of water-supply, especially after enough time has elapsed to enable the people to get over their prejudice in favour of well water as against pipe water.

No meeting of the Sanitary Board was held during the year, but papers connected with sanitation were circulated among the members.

Burma. The appointment of a sanitary engineer for Burma will, it is hoped, stimulate sanitary works in the towns of the province. He has already made progress in the elaboration of schemes for the improvement of the water-supply of Moulmein, Mandalay, Bassein, Meiktila, and Kengtung, and examined a drainage scheme for Prome town. The question of the extension of the Rangoon water-supply was still receiving attention. No original sanitary work of any magnitude was completed during the year. Twenty-two lakhs (£147,000), or about one-third of the income of the various funds, was expended on sanitary works, including the cost of the large reclamation schemes in Rangoon. It is considered that the proportion of income spent on sanitation in some towns, noticeably in the larger municipalities, might well be raised. The total spent in the municipalities, other than Rangoon, on conservancy rose from £22,000 to £24,000 the improvement being largely due to the introduction of better methods of disposal of nightsoil in the larger towns of Lower Burma.

The Sanitary Board, it is reported, did practically no work during the year.

Central Provinces. The municipalities in the Central Provinces expended 22 per cent. of their income on conservancy, drainage, and waterworks in the year 1898. The water-supply works in Jubbulpore and Khandwa were advanced, and those in Wardha and Bhandara were completed; progress was also made with the drainage of Jubbulpore. The Harda waterworks scheme was again in abeyance, owing to want of funds. No new villages were brought under the Village Sanitation Act during the year; the Act had been extended to 43 villages in previous years, and it is generally reported to work well. Village inspection notebooks have been started in all districts, but little was done towards keeping them up. The principle on which sanitary improvements in villages are undertaken is that the greater part of the burden should be borne by the village itself by cash contribution or by free labour. In 1898 both money and labour were scarce.

Assam. Excluding the towns of Hailakandi, Sunamganj, Karimganj, and Maulvibazar, which have no separate incomes of their own, the municipal authorities in Assam spent 46 per cent. of their income on sanitation, including expenditure on roads and bridges; excluding these items the amount spent on sanitation proper was equal to 43 per cent. of income. No extensive sanitary work was undertaken during the year, but the waterworks at Gauhati and Shillong, which suffered from the earthquake in 1897, were still under repair. The sanitary improvements effected in rural tracts consisted chiefly in the construction of masonry wells and the excavation and deepening of tanks at some of the larger villages. Sanitary inspection books were kept up in selected villages.

No meeting of the Sanitary Board was held during the year, but the opinions of members were obtained when any important sanitary question was under discussion.

Madras. In the Madras Presidency the municipal councils spent 54 per cent., and the district boards 6½ per cent., of their income for sanitary purposes, exclusive of plague measures. A large portion of this expenditure was on conservancy, but the expenditure out of income on water-supply altogether amounted to £17,000 in addition to that of Madras city. The water-supply schemes of Coconada, Tirupati, and Vizagapatam were in progress during the year, as was also the extension of the waterworks at Conjeeveram. The only drainage work of importance under execution during the year was the realignment of the intercepting sewer at Ootacamund. A decided advance was made in the matter of conservancy, and a large staff was maintained for scavengering. Village sanitary inspection report books were in use in all unions in 19 out of the 22 districts of the Presidency, the exceptions being Malabar, Anantapur, and Tanjore.

The Sanitary Engineering Department completed surveys for water-supply or drainage for three municipalities, and one scheme was still under consideration. Three estimates were submitted to the Sanitary Board, the most important being the water-supply scheme for Vizianagram, estimated to cost £19,000, and another for Bezwada, to cost £25,000. In addition to these, many other small projects were in execution or projected.

The Sanitary Board scrutinized, during the year, plans and estimates for 36 municipal and 78 local fund works, estimated to cost £32,600; they also examined and laid before Government schemes for the water-supply of Vizianagram, for the extension of the waterworks at Kurnool and Tanjore, and for the drainage of a portion of the town of Kumbakonam, besides proposals in connection with 19 other schemes.

In connection with the sanitation of Madras City several useful improvements were being carried out. The underground sewerage system was completed in Mylapore, this marking the first stage of the scheme for the drainage of the whole city; the laying of water pipes was continued. The total quantity of water supplied to the town was nearly 4 per cent. in excess of that of the previous year, but the analysis of the water showed that there was an increase in both free and albuminoid ammonia, which rendered it suspicious for drinking purposes.

Bombay.

In Bombay Presidency the municipalities allotted over 49 per cent. of their income for sanitary purposes, and the local boards 18½ per cent., though in neither case was the full allotment spent. The whole expenditure on sanitary purposes was £194,000, of which about a third was spent on improvement of water-supply, and rather more on conservancy. The large expenditure on plague precautions checked the prosecution of sanitary works. Some progress was made at Hyderabad, Yeola, Kirkee, and Akalkot in water-supply schemes, but elsewhere much needed projects in this direction had to be suspended; and the same may be said of drainage schemes. The Bombay Village Sanitation Act was introduced in 17 villages during 1898, making a total of 299 villages which have been brought under it since it was passed in 1889; while village sanitary inspection books have now been introduced into 3,199 villages, though little progress has been made in filling them up, owing to the disorganisation of ordinary sanitary work on account of plague. The Act provides for the establishment of a sanitary committee or a sanitary board, consisting of members chosen by the collector of the district, or by the Local Government, to supervise sanitary matters. Several committees have now been established, some being supported by local rates or voluntary contributions supplemented by Government and local fund grants.

In Bombay City 20 drainage works were in progress, several of which have been practically finished; on the Mazagon sewerage works over £18,000 had been spent up to date; £25,000 was spent during the year on the sewerage of Parel and other districts, chiefly in the purchase of machinery. Most of the other schemes were of considerable importance. The Shone system of sewerage at Colaba continued to work satisfactorily. The Corporation, having been unable to come to a decision on the surface and subsoil drainage scheme, had referred the whole question for advice and report to Mr. W. Santo Crimp. The waterworks were efficiently maintained throughout the year.

The Sanitary Board gave advice concerning several projects, including the waterworks at Kaira, Mehmadabad, Ahmednagar, and Belgaum, and drainage schemes for Poona City and Ahmedabad.

Berar.

The municipalities of Berar spent 50·7 per cent. and the district boards about 11 per cent. of their income on sanitary improvement, the proportion being in either case smaller than in 1897; but the amount in that year was swollen abnormally by expenditure more or less directly connected with famine relief. No new works of any great importance were undertaken during the year. The sanitary survey of selected towns and large villages made better progress, the stress of famine relief having been removed. The number of towns now surveyed is 37, and of villages 1,009, leaving two towns and 4,234 villages still to be surveyed. Village sanitary inspection books have been introduced in five selected areas in each district of the province, and it is hoped that the information thus recorded will be put to some practical use in future.

W. T. Ronson.

India Office,
October, 1900.

ABSTRACTS

OF

SANITARY AND OTHER REPORTS

FOR

1898.

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1898.

(*Surgeon-General Robert Harvey, M.D., C.B.*)

European Troops.

Sickness and mortality in 1898.

THE health of the European army of India was much better in 1898 than in the preceding year, though the constantly sick and death rates were still high as compared with the ratios of the decennium. The improvement is apparently connected with the fact that the progression of the seasons had become more normal. The dry parts of the year were somewhat quieter, hotter, and dryer than usual, and over the greater part of India the monsoon rain was above rather than below the normal. That the invaliding ratio was high, mostly from ague, and that sickness and mortality did not fall to the mean of recent years, were probably due to the sequelæ of the malaria of the previous year and to the after-effects of field service.

YEAR.	Strength.	RATIO PER 1,000 OF STRENGTH.				
		Admissions into Hospital.	Constantly Sick.	Deaths.	Invaliding.	TOTAL LOSS.
1886–95	677,877	1,457	83	15·16	24	39
1897	68,395	1,557	101	22·93	33	56
1898	67,741	1,437	90	20·05	38	58

The chief causes of admission were ague and venereal diseases. Among the diseases with increased admission rates were influenza, remittent fever, enteric fever, and hepatic abscess. On the other hand, the admission rates from cholera, small-pox, venereal diseases, dysentery, and diarrhœa were lessened. Ague caused 27 per cent. of the total sickness, and venereal diseases 25 per cent.

The chief causes of death were enteric fever, hepatic abscess, and heatstroke. Among the diseases with increased mortality were simple continued fever, heatstroke, respiratory diseases, tubercle of the lungs, enteric fever, and hepatic abscess. On the other hand, the mortality from cholera, small-pox, dysentery, diarrhœa, and malarial fevers was lessened. Enteric fever caused 51 per cent. of the total deaths, hepatic abscess 8 per cent., heatstroke 6 per cent., and dysentery 4 per cent.

The chief causes of invaliding were, in order, syphilis and gonorrhœa, malarial fevers, debility, dysentery, disordered action of the heart, and tubercle of the lungs; syphilis and gonorrhœa, and malarial fevers, being far ahead of the others.

In the following table the ratios of the four commands are placed side by side for comparison. Bengal had the highest mortality from tubercle of the lungs and from hepatic abscess, and the lowest from remittent fever and from pneumonia; the Punjab the highest from cholera, enteric fever, malarial fevers, heatstroke, pneumonia, other respiratory diseases, and dysentery; Madras the lowest from enteric fever, ague, tubercle of the lungs, respiratory diseases, dysentery, and hepatic abscess. The percentage of enteric fever in total deaths was highest in Bombay; of pneumonia in the Punjab; of dysentery and hepatic abscess in Madras. The total death rate of Madras, which was the lowest, only reached 31 per cent. of the height of that of the Punjab, which was the highest. Bengal had the highest constantly sick rate, the Punjab the highest admission and death-rates;

and the Punjab was the only command less healthy than in 1897, the others being more healthy.

Ratios of Commands.

	Ratio per 1,000 of the Average Strength.				
	Bengal Command.	Punjab Command.	Madras Command.	Bombay Command.	India.
I.—Strength	20,060	18,388	12,337	14,612	67,741

Hepatic abscess	2·09	1·25	1·13	1·57	1·52
All Causes	19·54	27·63	8·59	18·20	20·05

Burma.—The following table gives vital statistics of the European troops in Burma as a whole, whereas the table on the opposite page contrasts Burma Coast with Burma Inland. The ratios of 1898 are the lowest in the table. Burma in 1898 was distinguished by the prevalence of simple continued fever and venereal diseases :—

Period.	Strength.	Ratio per 1,000 of Strength.				
		Admissions into Hospital.	Constantly Sick.	Deaths from		
				Cholera.	Other causes.	Total.
1890	4,712	1,743	102	—	20·80	20·80
1891	4,623	1,589	92	2·38	17·74	20·12
1892	4,316	1,491	91	—	14·83	14·83
1893	3,928	1,461	96	·25	12·73	12·98
1894	3,940	1,465	93	·25	9·39	9·64
1895	4,045	1,410	96	·99	8·41	9·39
1896	4,174	1,514	109	·48	6·71	7·19
1897	4,060	1,467	107	—	10·84	10·84
1898	4,069	1,167	79	—	6·39	6·39

Field Forces.—Of the forces which were on field service in 1898, the Malakand Field Force was broken up on the 22nd January, 1898, and out of it was formed the Malakand Force; the Tirah Field Force was broken up on the 9th April, and out of it was formed what was called at one time the Khyber Force and at another the Khyber Brigade. The health of the Tirah Field Force was better than in the preceding year. Adding together for 1898 the Field Forces and the forces by which they were succeeded, it is found that health in 1898 was better than in 1897. The Tirah Field Force, the Khyber Force, and the Malakand Force suffered heavily from enteric fever.

Geographical Groups.—The following table shows that, judging by the constantly sick rate, Burma Inland and Gangetic Plain were the most unhealthy groups for the decennium, and Hills and Deccan the most healthy. It also shows that the 1898 constantly sick rate of every group, except the first three, was higher than its corresponding decennial ratio, and that the rise was greatest in the case of the Deccan, Central India, and Indus Valley groups. As compared with the decennial ratios, there was increase of cholera mortality only in Bengal-Orissa, absence of cholera mortality, as usual, in Western Coast, and reduction in all other groups; while there was decrease of enteric fever mortality in Groups I., II., IV., X., and XII*b*., and increase in all the others, the mortality being greatest in Groups XII*a*., VII., V., and VIII.

In the following table the vital statistics of the groups for 1898 will be found placed side by side to facilitate comparison. Gangetic Plain had the highest constantly sick rate, and Indus Valley the highest admission and death rates; Hills the lowest constantly sick rate, Western Coast the lowest admission rate, and Burma Coast the lowest death rate. Burma Coast had the highest admission rate from simple continued fever and small-pox, and the lowest from ague; Burma Inland the lowest from tubercle of the lungs and from respiratory diseases other than pneumonia; Bengal-Orissa the highest from dysentery and hepatic abscess; Gangetic Plain the highest from tubercle of the lungs and venereal diseases; Upper Sub-Himalaya the highest from cholera; Indus Valley the highest from ague, remittent fever, pneumonia, and other respiratory diseases, and the lowest from simple continued fever and venereal diseases; Deccan the highest from influenza; Western Coast the lowest from enteric fever and hepatic affections, and nearly the lowest from ague; Southern India the highest from congestion and inflammation of the liver, and the lowest from diarrhœa; Hill Stations the highest from enteric fever and rheumatic fever, and the lowest from dysentery.

The percentage of enteric fever to total admissions in 1898 was greatest in Hill Stations; of ague in Bengal-Orissa and Indus Valley; of remittent fever in Indus Valley; of simple continued fever and venereal diseases in Burma Coast; of dysentery and hepatic abscess in Bengal-Orissa; of enteric fever, pneumonia, and diarrhœa in Hill Stations; and of other respiratory diseases in Western Coast.

Stations.—The highest ratios among the large garrisons with a strength of over 1,000 were those of Peshawar and Quetta (over 40), Lucknow (over 30), Umballa, Agra, and Rawalpindi (over 20); and all, except that of Agra, which was much reduced, were higher than the corresponding ratios of 1897. The greatest increase was in the case of Quetta, and was due especially to enteric fever, and in a less degree to malarial fevers, respiratory diseases, hepatic abscess, and dysentery. Lucknow also had a great increase of mortality from enteric fever; and Rawalpindi a great increase from abscess of the liver. Though the death ratio of Peshawar was highest of all, it showed the least increase over the ratio of 1897. Agra, Umballa, and Peshawar were also in this black list in last report. The health statistics of Umballa, Rawalpindi, and Peshawar are said by the medical officers to have been unfavourably affected by the return or reception of broken-down men from frontier field service; and at eight other stations the same complaint was made.

Regiments.—The statistics of individual regiments and of the different arms of the service show that the infantry had, as in the preceding three years, the highest admission and constantly sick rates; and the cavalry the highest death and invaliding rates. The highest constantly sick rate was in the 80th Battery, Field Artillery, at Jhansi; the highest among cavalry in the 5th Dragoon Guards at Meerut; and the highest among infantry in the 1st Battalion of the Bedfordshire Regiment at Meean Meer. The highest death rate was in the 2nd Battalion of the Yorkshire Regiment at Peshawar, and was due to enteric fever and heatstroke. The 2nd Battalion of the Oxford Light Infantry at Lundi Kotal and the 1st Battalion of the Wiltshire Regiment at Quetta had also high ratios due to enteric fever. The 9th Lancers at Muttra and the 25th Battery, Western Division, had the highest ratios (due to enteric fever) in their respective arms of the service.

Principal diseases: Influenza.—Sickness and mortality having been studied in their relation to India, to commands, to geographical groups, to stations, and to regiments, it will be convenient now to discuss the statistics of some of the chief diseases. At the end of 1897 and the beginning of 1898 influenza was falling. It began to rise again in February 1898, and reached its maximum for the year in April. There was very little in the second half of the year. The following table shows the increase of total in 1898. It also shows the monthly progress and the annual fluctuations of the disease since 1890, the first epidemic year:—

Period.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.	Per 1,000 of strength.
1890	—	3	473	1,451	248	69	13	2	3	—	—	1	2,263	33·4
1891	1	—	1	16	77	91	112	29	20	2	2	21	372	5·5
1892	113	53	354	241	57	4	32	8	—	—	—	—	862	12·7
1893	1	—	—	15	4	—	—	—	—	—	—	1	21	·3
1894	7	9	12	70	101	30	7	7	—	2	—	—	245	3·4
1895	14	7	52	156	66	35	17	1	5	13	23	165	554	7·8
1896	262	65	140	30	12	7	3	3	88	128	50	20	808	11·5
1897	12	10	31	9	11	30	8	8	—	54	87	12	272	4·0
1898	7	19	82	213	162	57	6	—	1	—	9	8	564	8·3
Total	417	166	1,145	2,201	738	323	198	58	117	199	171	228	5,961	

The actual maximum of the individual years of the nine occurred in various different months, but over the nine year period as a whole the greatest numbers of cases occurred in April and March, and the smallest numbers in August and September: 84 per cent. of the whole in the first six months of the year, and only 16 per cent. in the last six months. Geographical Groups I., II., V., VI., VIII., IX., XI., XII*a*., and XII*b*. were attacked

both in 1897 and in 1898 ; Group IV., which had escaped in 1897, was affected in 1898 ; Group VII. escaped in both years ; while Group X. was spared in both years, as well as in 1896, 1895, and 1894. It is not known why this last group, which contains the European garrison of Bombay, has been so long free from influenza. Twenty-five stations were attacked in 1898, against 12, 19 of them suffering only in 1898, and six in both years ; while six escaped that had been affected in 1897. Belgam, Ahmednagar, Sitapur, Wellington, and Secunderabad had the greatest numbers of cases. At some stations the beginning and the end of the outbreak were abrupt, at others more gradual ; but nowhere did two distinct outbreaks occur in the year. The average number of men constantly sick with influenza was 25, against 10 in 1897, and the average duration of a case 16 days, against 13. The returns deal, of course, only with those cases which were admitted into hospital. The only death returned as directly due to influenza occurred at Belgam. It is mentioned that at Belgam there were other cases besides those admitted to hospital. At page 74 is given a table showing the relation, year by year, of influenza to pneumonia, and of the influenza of the European troops to that of the native troops and to that of the prisoners. The influenza admission ratio of the first was the same as that of the second, much less than half that of the third. The likeness of some of the cases to dengue was noted at Barrackpore.

Cholera.—General questions regarding the etiology, spread, and prevention of cholera, and the circumstances, so far as they are of importance, attending the occurrence of cases of 1898, will be found discussed under Chief Diseases, page 94. The amount and proportion of cholera were much less than in the previous year, and the ratios were much below those of the decennium, as may be seen in the following table :—

Period.	Admissions.		Deaths.	
	Number.	Per 1,000 of strength.	Number.	Per 1,000 of strength.
1886–95	1,280	1·9	901	1·33
1897	117	1·7	80	1·17
1898	17	·3	14	·21

As regards the distribution of the cholera of 1898 by stations and seasons, the monthly maximum was only 11, and was reached in May ; and in no less than eight months of the year cholera was absent. Umballa with ten cases suffered most, seven of the cases occurring in the 3rd Battalion of the Rifle Brigade.

Small-pox.—The admission rate from small-pox was reduced from 0·4 to 0·03, and the death rate from 0·06 to 0·00. There were only 2 cases with no death against 24 cases with 4 deaths. The ratios were, of course, much below the decennial ratios of 1886-95. Rangoon and Sialkot had each one case, the former station belonging to Burma Coast and the latter to Upper Sub-Himalaya.

Ague, Remittent Fever, Simple Continued Fever, Malta Fever.—Ague gave rise to over 27 per cent. of the admissions from all causes. That the admission ratio did not fall more seems to have been largely due to relapses among those who had contracted the disease in the preceding year.

Period.	Intermittent Fever.		Remittent Fever.		Simple Continued Fever.	
	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.
1886–95	353	·18	9	·54	57	·04
1897	395	·41	25	·60	43	·01
1898	394	·30	33	·37	43	.06

The ratios were above those for the decennium. In 1898 the ague ratios were high in ndus Valley, Bengal-Orissa, and Upper Sub-Himalaya, and low in Burma Coast, Western Coast, and Burma Inland. And that this is a usual state of things as regards the first, third, fourth, and fifth of those groups, may be seen from the following :—

Period.	Ratio per 1,000 of Strength.												
	I.	II.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII*a*.	XII*b*.	
	Burma Coast and Bay Islands.	Burma Inland.	Bengal and Orissa.	Gangetic Plain and Chutia Nagpur.	Upper Sub-Himalaya.	North-Western Frontier, Indus Valley, and North-Western Rajputana.	South-Eastern Rajputana, Central India, and Gujarat.	Deccan.	Western Coast.	Southern India.	Hill Stations.	Hill Convalescent Depôts and Sanitaria.	India.
1886–95...	194·5	531·2	381·8	216·9	465·5	632·4	496·9	228·0	164·3	119·0	291·0	320·4	352·9
1897 ...	47·4	132·6	383·9	246·7	422·6	761·8	584·2	333·3	182·2	139·4	128·1	158·7	394·7
1898 ...	56·3	171·4	603·5	314·8	550·3	766·3	499·1	320·6	115·0	278·1	224·8	443·3	394·0

It will be observed that the high ratio of Bengal-Orissa is unusual. All the stations in the group participated in the increase. The medical officer of Barrackpore explains that a large proportion of the cases were relapses in men infected the previous year, and that the type of disease was milder than in 1897. The fever at Dum Dum is said to have been largely due to the receipt of infected men from Barrackpore; and with regard to Calcutta it is stated that there had been practically no cold weather, and that the damp fogs had been a prolific source of the disease in men weakened by the long-continued hot weather. At ten stations the original infection of men suffering in 1898 is said to have been contracted on field service. Proximity of irrigation canals was blamed at Kirkee. On the other hand, reduction of ague was at Kurrachee ascribed to the Indus having overflowed less than usual, and at Meiktila to the water having been boiled. Those officers who mention the prophylactic issue of quinine speak of it as having been beneficial.

The most malarious month of 1898 was November, and the least malarious February. A comparison of the figures for 1898 with those for 1897 supports the view that the malarial fever of 1898 was largely a product of the malaria of 1897, because the numbers of cases in the earlier months of 1898 were high, while those in the usually malarious months were low.

Morbidity from remittent fever increased in 1898, while mortality diminished. The disease was most prevalent at Peshawur and in the Khyber Force and Brigade. The geographical groups which showed the greatest increases were VII. and XI. The medical officer at Peshawur remarks that the remittent fever was mild, there being only 7 deaths in 1,116 cases, or a little over 0·6 per cent. The case-mortality for India was also only just over 1 per cent. Remittent fever in 1898 was most prevalent in May, and least prevalent in February. This distribution is not the same as in 1897, probably on account of the continuity of malarial action from 1897 into 1898; and this difference of distribution, therefore, supports the diagnosis of these remittents as malarial. The records of the *post morten* examinations also on the whole supports the diagnosis, though in one case ulceration of the large intestine with abscess of the liver was found, and in two others ulceration of the intestine unlike that of enteric fever.

The admission ratio from simple continued fever was slightly reduced, while the death ratio increased. It was most prevalent in Burma Coast, Southern India, and Western Coast. Four deaths were returned, and in the three *post mortem* records which have reached this office no definite lesions are described. The medical officer of Barrackpore complains that danger to the community is often caused by wrongly diagnosing mild cases of enteric fever as simple continued fever or ague. In the Cherat, Madras, Bellary, and Mandalay reports it is noticed that the relative numbers of cases of simple continued fever, ague, remittent fever, and, it might have been added, enteric fever, vary with a change of medical officer; and the medical officer of Bellary illustrates this by indicating his opinion that simple continued fever is no doubt of malarial origin.

Two cases of Malta fever were returned, one from Deolali and one from Nowshera. The patient at Deolali had come from Gibraltar. With regard to the case at Nowshera the medical officer says :—

> The patient, of the 1st Battalion of the Dorsetshire Regiment, was admitted on December 2nd, 1898, complaining of acute pain in left hip and knee. He arrived in India on November 18th, 1898, from Malta, where he had been 92 days in hospital with Mediterranean fever. Since then he had had slight recurrence of pain in his joints from time to time. The present illness started at Deolali, and he gradually got worse till admission. . . . . In view of the previous history the disease was diagnosed as Mediterranean fever.

Enteric Fever.

Since last report was written there has been no striking discovery in the domain of enteric fever etiology. Perhaps the points that have come most to the front are the results of the continued researches as to the infectivity of the fæces and urine, especially of the latter, and the insistence upon the reality and not altogether inconsiderable frequency of sick-room infection.

Fæces.—The general conclusions arrived at by Horton Smith from his examination of fæces are as follows : —

> The stools of a typhoid patient separated from the urine contain typhoid bacilli in fair quantities, demonstrable by our present methods up to about the beginning of the third week. After this date the number begins rapidly to diminish, so that our methods no longer avail as a rule to find them. If, however, a relapse occurs, it may be preceded by a recrudescence of the typhoid bacilli, which can then be found again in the fæces ; but during the greater part of the relapse itself and throughout convalescence the typhoid bacilli cannot be found in the stools. It follows from the above that the stools of a typhoid patient must always be regarded as highly infectious during the early stages of the disease, and may again become so in connection with the commencement of a relapse. This highly infectious character, however, soon becomes greatly diminished, though how soon the stools become absolutely harmless cannot as yet be settled by bacteriology. Finally, when typhoid bacilli have been described in the fæces long after defervescence—*e.g.*, in Lazarus's case, 41 days after—we are dealing almost certainly with fæces contaminated with urine, and not with pure fæces.

The results were obtained from the examination of 29 stools, three before the eighteenth day and 26 after, by a fully controlled Elsner method ; and the results of Pollak, Jemma, and Richardson, are also quoted ; all going to show that during the first two weeks of enteric fever, but, apparently, more often towards the end of the second week than earlier, the enteric bacillus can be demonstrated in the stools if sufficient care and trouble be taken. Of the 29, the only stool belonging to a later day of the disease than the seventeenth in which a positive result was obtained was one voided just before a relapse occurred. Some of the older findings of enteric bacilli at late periods of the disease or in convalescents were vitiated by the fact that no care was taken to obtain the fæces without admixture of urine, an excretion which, as will be seen hereafter, is apt to contain the bacillus at late periods. It is a fact that, *post-mortem*, enteric bacilli can often be found in the gall-bladder, even in pure culture, at a time when they can no longer be found in the fæces. Why in such cases they have not continued to appear in the fæces is not at present explicable.

Urine.—With regard to the urine, Horton Smith's general conclusions are :—

> (1) It can no longer be doubted that typhoid bacilli occur in the urine of typhoid patients, probably in about 25 per cent. of all cases. (2) For the most part, though present in such numbers as to be demonstrated bacteriologically with the greatest ease, they are not present in sufficient quantity to alter the naked-eye appearance of the urine. In a smaller proportion of cases, however,—probably about 5 per cent. of all typhoid cases—the urine is rendered turbid by their presence. They are nearly always in pure culture. (3) They occur first late in the disease, rarely, if ever, before the third week, and may make their first appearance during convalescence. (4) They generally remain present for some considerable time, for some weeks or even months. (5) The character of the urine does not assist in diagnosing the condition (unless, of course, it be rendered turbid by the bacilli). It may contain no albumin, often contains but a trace, sometimes has a good deal, and sometimes has pus ; all of which conditions occur quite apart from the presence of typhoid bacilli in the urine. (6) The prognosis of a case is not rendered more grave by the occurrence of this condition.

"The urine," continues Horton Smith, "must be regarded as highly infectious, and the same precautions should be taken with regard to it both during the disease and also during convalescence as have now for some years past been adopted in the case of the fæces." He then makes a strong appeal for the routine employment of urotropine after the method of Richardson. In the course of his paper he refers to his own previous work, and to that of Petruschky and of Richardson, papers by all of whom were referred to in last report. He agrees with Petruschky that the enormous excretion of enteric bacilli in the urine that occurs in some cases may be intermittent, and points out that it must therefore be due to some local change in the urinary tract, and not to a filtration of bacilli from the blood. As Opitz says, there is no physiological elimination of bacteria by the kidneys, and bacteria appear in the urine only when the vessel walls and the renal epithelium have

been injured. The appearance of the bacilli in the urine has not been observed earlier than the 15th day; but it is said that the urine may continue to contain bacilli for months or even years.

Richardson has published several papers on the subject. In one series he obtained a positive result in 9 patients out of 38 and in 44 specimens out of 172. When the bacilli were present at all, they were in large numbers and almost in pure culture. They did not appear until a late stage of the disease, and usually continued to be excreted up to late in convalescence; so that both during the disease and during convalescence the urine should be carefully disinfected. The presence of enteric bacilli was always accompanied by that of albumen and casts, although all urines with albumen and casts did not contain enteric bacilli. The earliest dates at which bacilli were found were the 15th and the 24th days of the disease, and in 5 out of the 7 patients who survived the bacilli were still present on discharge from hospital. In another series he had positive results in 7 out of 24 cases and in 26 out of 96 specimens, and the accompanying circumstances were the same as in the other series. The enormous numbers of bacilli present often caused cloudiness of the urine, and perhaps the bacilli may have multiplied in the bladder. In a third series of 66 cases he found the bacillus in the urine in 14, sometimes in enormous numbers. The bacilli can persist for weeks and months, and in one case they were found in the urine of a man who, since an attack of enteric fever five years before, had suffered from urinary trouble (probably specific enteric nephritis). As those who suffer or have suffered from enteric fever may remain so long dangerous, every patient should receive 30 grains of urotropine daily for 10 days as convalescence approaches, beginning with the third or fourth week.

Renal enteric fever is also spoken of; by which appears to be meant ambulant cases of enteric fever with renal symptoms, the diagnosis being made by the finding of the enteric bacillus in the urine.

Infectivity of Fæces and of Urine compared.—Horton Smith notices that whereas the fæces contain the bacilli in apparently every case, the urine is infective probably only in about 25 per cent. of cases; that typhoid stools are most dangerous within the first three weeks, while typhoid urine only becomes dangerous towards the end; that typhoid stools may contain considerable quantities of typhoid bacilli, but rarely, if ever, such myriads as may be present in the urine. He continues:—

In conclusion we may ask which excretion must be regarded as the more dangerous and chiefly responsible for spreading the disease. It would seem on the whole that the palm must be given to the urine, and this partly on account of the enormous number of bacilli which may occur in it, and partly on account of the nature of the excretion itself. Thus, the stools by their colour and odour at once attract attention, so that the slightest soiling of the linen is at once noticed, and the damage rectified. But the same cannot be said of the urine. A minute drop from a suitable case may contain some 6,000 bacilli adhering to the end of the penis or to the vulva after micturition. It would infect the linen, and could not but escape detection. It is probable, indeed, that in such cases we have the explanation of the fact that even after all precautions have been taken, those attending on typhoid patients not so very rarely catch the disease. It would seem in fact at the present moment that this occurrence must be sometimes unavoidable. Indeed, when we come to think of the matter, it is really astonishing, considering the opportunities of infection which undoubtedly exist, that these cases do not occur more often. It is a strong argument in support of the view that some other conditions must pre-exist, possibly in connexion with the bacterial flora of the alimentary canal, without which typhoid fever will not occur, even should the typhoid bacillus be introduced.

The danger to water-supplies of such infective urine has been pointed out by Petruschky and others. Kübler and Neufeld, from the circumstance that no colon bacilli accompanied the enteric bacillus in the water of a certain well, concluded that the contamination had more probably been effected by urine than by fæces. The presence of the colon bacillus in the water would not, however, have proved that the water had been infected by fæces and not by urine, because the presence of the colon bacillus has been reported in urines, as mentioned in reports of former years.

Sick-room infection.—In a careful paper read before the British Medical Association, Dr. Peck gave the following table to illustrate his experience as Medical Officer of Health of the Chesterfield Rural District:—

Soil infection	9	cases,	equal to	4·37	of	the	whole.		
Drain effluvia	21	„	„	10·20	„	„			
Pollution of water-course	9	„	„	4·37	„	„			
Manure	6	„	„	2·91	„	„			
Water	1	case	„	0·50	„	„			
Importation	25	cases	„	12·13	„	„			
Sick-room infection	28	„	„	13·50	„	„			
Several possible causes	69	„	„	33·50	„	„			
No ascertainable cause...	38	„	„	18·44	„	„			
TOTAL	206	cases							

His conclusions are :—(1) That sick-room infection is more common than is supposed, and that the danger of it does not receive the amount of attention it deserves. (2) That sick-room infection is much commoner in the small and often crowded houses of the poor than in the larger houses of the well-to-do. He also quotes Dr. Boobbyer's experience at Nottingham as to the greater frequency of enteric fever in houses of small accommodation. Boobbyer considers that the disease is communicable by personal intercourse even in well regulated hospitals, and more so in the confined dwellings of the poor ; and Parsons that harm is done by underrating its communicability. Seaton and Bulstrode share in the same views, and Blake supports it by a record of cases. Drs. Barrs, Pearson, and Willoughby maintain the usual view, that when a person contracts enteric fever directly from the sick, it is due to his own disregard of precautions of cleanliness ; but S. Cameron and Evans allow in addition a certain amount of aërial convection, much less of course than in the case of small-pox. From Italy it is reported that in a certain institution the passing of an imperfectly cleansed clinical thermometer from anus to anus was a means of spread. In investigating an outbreak of 13 cases in Germany, Kübler and Neufeld came to the conclusion that while the second case arose from pollution of the well by the dejecta of the first case, the remaining 11 cases were due to direct or sick-room infection.

Flies.—It has been found that the virus of enteric fever is not weakened by passing through the alimentary canal of flies. It is believed therefore that flies may convey infection not merely by carrying it adhering to the outside of their bodies, but also by ingesting it from fæces, urine, &c., and subsequently dejecting it on to articles of food or drink destined for consumption by man. The large part that flies were, as the result of investigation, thought to have taken in the spread of enteric fever in the American army camps at the time of the Cuban War, was mentioned in a former report. Nuttall agrees with Veeder that flies are not sufficiently thought of, while water is always blamed. V. Poore, on the other hand, says—

> We hear much about flies conveying fever, which may be true ; but we must always bear in mind what I feel inclined to call the excessive specialism of Nature.
>
> Insects which feed on dung and carrion are seldom attracted by the food of human beings, and I confess to being somewhat sceptical as to the accidental conveyance of infection by "flies" which heedlessly buzz first into the fæces and then into the milk.

Medical officers in India frequently refer to the danger from flies that come from the latrines and alight on food or drink in the cook-rooms or barracks.

Dust.—Kenwood speaks of the danger of the enteric bacillus getting into the dust of the room, and thus into food and drink ; Nollet describes the finding of the bacillus in the interstices of the woodwork of a barrack in France ; Sanglé-Ferrière and Remlinger assert that during an epidemic in Tunis they found the enteric bacillus, and in a second epidemic there the colon bacillus and an enteric-like bacillus, in the dust of the air, though not in the water, cases of fever having previously occurred among the inhabitants of the ground that was defiled with excrement ; and Newman in a description (characterized by *Nature* as a little difficult of comprehension) of an experiment of his own seems to indicate that in the perfectly still atmosphere of a bell-jar the enteric bacillus, once it had become dry enough, was able to ascend into the air, and contaminate sterilized milk, and also water, contained in small vessels under the bell-jar. On the other hand, Neisser, as has been noticed in former reports, considers the conveyance of enteric fever by room dust as impossible, because the degree of drying necessary before it can be carried about in dust is fatal to the bacillus. The mode of infection by the spray of coughing, proved for some diseases, can, as far as present knowledge allows judgment, have little bearing on the conveyance of enteric fever ; unless, perhaps, when pneumonia is present. (*See* under "The Bacillus in Sputum.")

Soil.—S. Martin, continuing his well-known investigations, found that in sterilized samples of earth from cultivated districts and preserved from drying, the enteric bacillus not only retained its vitality for 456 days, but spread through and over the whole soil. Even in dust-dry similar samples it lived for 49 days. The experiments were successful not only at incubation temperature but also at average outside temperatures. In sandy or turfy virgin soil the bacillus quickly perished. From inoculated unsterilized samples of such soils as are after sterilization good for growing it, the enteric bacillus could be recovered after 50 days, though, owing to the presence of the colon bacillus, the process was very long and difficult.

It has been said on the one hand that a water-logged soil rich in organic matter, on the other that a soil at a temperature over 60° F. and with moisture under saturation, ought to be favourable to the enteric bacillus ; but in India the disease seems

most prevalent in the drier parts of the country, and is very commonly at its maximum in the driest time of the year. As indicating a connection of enteric fever with the soil, it has been pointed out by Haffkine that the enteric virus may stick to the infected locality for years, and may, in spite of improvement in the water-supply, cause a continuous incidence of the disease, for which, occasionally, nothing short of complete evacuation of the locality is an effective remedy. It does not seem to be suggested that there is anything mysterious in the connection between enteric fever and soil, or that any deep geological problems are involved. The whole danger lies in the defilement; though that may perhaps be influenced in extent or duration by local geological formation, as contended by Sir Charles Cameron in the case of Dublin. At any rate, till more is really known on the subject, most sanitarians will be inclined to share in and act on the belief of Sir Charles Cameron that "the cleaner the soil we live on, the longer we are likely to live on it."

Water Filters and Allied Topics.—As Houston says, when the bacteriology of soil is better known, it will be possible to prophesy the bacteriology of a water, provided its origin is known. Many of the bacteria found in surface soils do not commonly occur as water organisms: hence the discovery of these particular organisms would indicate contamination with flood water. He found that the colon bacillus and the bacillus of Gaertner were more easily isolated from recently manured soil, and Klein agrees with him that "in the *bacillus enteritidis sporogenes* (Gaertner) we have a new test for contamination of soils, and therefore of waters derived from them." In investigating the recent outbreak at Belfast, Lorrain Smith found in the spleen of those who died the enteric bacillus and the colon bacillus, but in the water only colon bacilli and not the enteric bacillus. But because some of these colon bacilli occurring in the water were pathogenic to animals and reacted by the clumping test to enteric serum, he concluded that they were directly concerned in the infection. His general conclusions were—

1. In the presence in the water of typical bacilli of the coli communis group we find evidence of contamination with intestinal excreta. 2. Certain of these bacilli exhibit their relationship to the process of infection in typhoid fever: (*a*) by their lethal effect on small animals, (*b*) by showing the reaction of infection when exposed to the blood of typhoid patients. . . . Short of discovering in the water the typhoid bacillus also, and thereby giving absolute proof regarding the primary cause of the epidemic, I know of no stronger bacteriological evidence than that which I have adduced in favour of the conclusion that this contamination of the water is one of the causes of the outbreak of the disease in Belfast.

On the other hand a reviewer of Lorrain Smith's report, on the ground that the incidence of the disease was unequal in the city, and that the City Gaol and the asylum escaped, considers that the outbreak was more probably due to soil pollution. In criticising the report on the Maidstone epidemic Sims Woodhead stated that the presence of the *bacillus coli communis* should be regarded as evidence of contamination, provided that the bacillus found had certain biological characters and was pathogenic to animals. Kübler and Neufeld, investigating an outbreak in Germany, isolated from the well the enteric bacillus, and four weeks later a bacillus which, though not pathogenic to animals, agreed with genuine enteric bacilli in appearance, in motility, and in behaviour to the chemical tests, and was also agglutinated by enteric serum. It was apparently an enteric bacillus of diminished virulence. They point out that for the positive identification of enteric-like bacilli found in water, the serum test is absolutely indispensable. Their claim to be the first to have proved the presence of the enteric bacillus in water by a faultless method of diagnosis will probably be disputed by Hankin in India and by others in Europe. The success of the bacteriological examination a month or more after the supposed time of pollution of the water was supposed to point to original infection by large numbers of bacilli, and this, together with the absence of the colon bacillus, seemed to indicate pollution by urine (see under "Urine"). The well was supposed to have been infected by the washing near it of the sick-room utensils used by the first case; but after the occurrence of the second case it was put out of use, boiled water was issued, and the stools were treated with milk of lime. Nevertheless 11 more cases occurred, which were attributed to sick-room infection. During the time the well was out of use a stranger, ignorant of the circumstances, drank of it, and got enteric fever. As a rule, water is not examined till too late—after the incubation and outbreak, or even after the subsidence of the disease; at least, that is the reason usually given for failure to find the microbe. Constant examination, or a lucky investigation after a copious pollution, would seem the circumstances under which success is most likely. If the chances against the success of bacteriological examination be so great, still less can chemical examination, though it may indicate danger, ever tell with certainty that water is free from specific infection. Klein and Houston infected sterile distilled water with

sewage in varying degrees representing dilutions of sewage ranging between 1 in 100 and 1 in 20,000. Chemically they found that the majority of these waters would have been classed as at least organically safe drinking-water, but in each and all of them the *bacillus coli* and the *bacillus enteritidis sporogenes* were detected. The presence in water of the *bacillus pyogenes cloacinus*, isolated by Klein from sewage, would also be condemnatory. Blaxall, in noticing the rarity with which the enteric bacillus is found in suspected water, and offering the usual explanation, contends that such water rarely fails to show the presence of the colon bacillus and other bacteria that point to excremental pollution. An opinion to somewhat the same effect was quoted in the report for 1895, from McWeeney. Abel, on the other hand, remarks that as the *bacillus coli* is everywhere, its presence in water does not necessarily mean anything serious. The truth seems to be that, while the mere presence of the colon bacillus in water is insignificant, its constant presence or its presence in large numbers, especially in a form that is pathogenic to animals or re-acts with enteric serum, is a sign of danger past or present or possible.

Both the enteric bacillus and the colon bacillus are distinguished from the natural water-microbes by their inability to live in distilled water for long periods. The enteric bacillus, if shaken in sterilized water, soon perishes; and, according to Frankland, Ackermann explains this by supposing that the flagella are nutrient rootlets, and get broken off in the shaking, so that the bacillus can no longer absorb food. This however, is a mere speculation.

In contradiction of the results of other observers, Malfitano reports that no permanent biological modification in the bacteria employed was observed to result from exposure to compressed carbonic acid gas, though the pressure was raised to 55 atmospheres. Nor was he more successful when he exposed the bacteria to the interrupted action of the gas; and he concludes therefore that the purity of aërated water depends on the care taken by the manufacturers to sterilize the original fluid. The enteric bacillus is said to have been isolated from impure ice.

M. Treelle reports that in 1893 a violent epidemic broke out in Tiemcen. One of the barracks was supplied with water filtered through Pasteur filters, and yet only in that one did an epidemic of enteric fever break out. The other barracks were not provided with filters. In an epidemic at Castres in 1897, the barracks outside the city, provided with water filtered through Pasteur filters, were severely tried, whereas the scholastic establishments in the centre of the city entirely escaped. Again, Dr. Nollet says:—

> After a period of infatuation the Chamberland filter no longer commands the confidence of hygienists. The *bougie Chamberland* may be useful in a laboratory, but it is by far too fragile for a barrack-room. A filter with a fissure through it, or one badly looked after, is worse than none at all. If, however, it should be decided to retain the Chamberland *bougie* in spite of its many defects, then each one in use should be tested daily by the regimental medical officer.

On the other hand, Defries endeavours to prove by statistics that the Pasteur-Chamberland filter has really been of use in the French army. The Berkefeld filter, Lunt states, after a few days' use, lets through water-bacteria, but not the colon bacillus, the enteric bacillus, or the cholera vibrio, at least not for some weeks. So, too, van't Hoff found that with sand-filtration too slow passage of the water was as bad as too quick, probably because the delay allows the bacteria to multiply in the stagnated water and in the filter. Delépine is quoted as showing that it is very difficult to purify by sand-filtration water that has once been polluted; filtration does not give absolute security, and when the water is unpolluted it is unnecessary. Instead of filtering the water after it has been polluted, it is better to protect it from pollution at the source.

It has been said that "water polluted with sewage at its source produces enteric fever at its distribution," some understanding this to mean sewage as sewage, others considering it to be true only of sewage containing the enteric bacillus; but, while that is the history of explosive outbreaks, it seems to be equally a fact that "endemic and annually recurrent prevalence of enteric fever depends on local and permanent insanitary conditions." As Haffkine says, while cholera infection seems to be almost exclusively confined to the water-supply, in the case of enteric fever, improvement of the water seems to leave intact a large number of other sources of danger, which have as yet escaped recognition. In fact, it is coming to be more and more clearly perceived that enteric fever is not simply and solely a water-borne disease. However, on the other hand, S. Cameron suggests (and this seems to have been the belief also of the late E. Hart) that polluted water containing bacilli in too small numbers to produce an explosive outbreak may yet cause cases, attacking those who drink much of it, or those who are very susceptible.

Various experiments have been made by the use of the *bacillus prodigiosus*, aniline dyes, kerosene oil, or easily recognizable chemical substances, as to the filtering power of the ground, and as to the possibility of the contamination of well water by the way of surrounding soil. The result of such experiments seems to be on the whole that the danger is greater than had been suspected. The actual or possible existence of faults, sun-cracks, rat-holes, or worm-burrows has to be reckoned with.

With reference to a remark made on page 28 of the report for 1897, Mr. Hankin has pointed out that, while Abba's experiments were made with Pasteur-Chamberland bougies, his own were done with the ordinary coarse country earthenware. A note by Mr. Hankin on the detection of the enteric bacillus in water, etc., is printed as an appendix to this section (not reprinted).

Milk and Butter.—Bolley and Field found that, after the enteric bacillus had been introduced into butter, 10 days was the longest time it could be detected. When, however, the cream was infected with enteric germs before churning, they could be discovered in the butter even after three months. They report that the enteric bacillus does not grow in butter if the buttermilk has been thoroughly worked out of it, but that if it is left, they increase ; that in sterilized milk the bacillus can exist for upwards of four months ; that innoculated into freshly-drawn milk, the bacillus can be demonstrated as long as three months afterwards ; that no types of bacteria were met with in milk which proved capable of overcoming the enteric bacillus ; that the same bacillus, when inoculated even in comparatively small quantities into sour milk, took wellnigh complete possession of the liquid, becoming almost a pure culture. As in the case of water, it is not usual to succeed in finding the bacillus in suspected milk, even when the chain of evidence seems otherwise complete, and when the disease appears to be stopped by measures directed to the milk-supply. An outbreak affecting 42 out of 45 inmates of a pauper asylum was traced by Naegeli to the man who milked the cows, and who, though he had never knocked off work, was shown by Widal's test to have been an example of ambulant enteric fever. A similar chain of events was observed in Glasgow.

Sewer-gas, Foul Air, Insanitation, Geology.—The enteric bacillus has never been discovered, and according to present knowledge is not likely to be discovered, in sewer air. But cases still continue to be reported in which medical men are convinced of the casual relation of sewer gas to the fever. Thus, Wyatt Smith, stimulated by the publication by Nash of several series of cases of different diseases supposed to have been produced by sewer air, places on record an instance in which three cases seem to have so originated. The record is not quite convincing, owing to the absence of stringent proof that the disease could not have been contracted otherwise than by inhalation. There seems to be spreading abroad a revived opinion that sewer air inhaled, or sewage-polluted water drunk, even if the enteric bacillus be absent from them, can produce or induce enteric fever. But, so far as is known, there is no enteric fever without the Eberth's bacillus. In such cases the bacillus must, therefore, come in somewhere. The explanation, accordingly, may be that the bacillus, perhaps in an attenuated condition, is already present in the bodies of the patients ; and that the chemical products of putrefaction, inhaled in the sewer air, or ingested in the sewage-polluted water, depressed the human organism, or exhalted the microbe, or both ; thus giving an advantage to the microbe, and enabling it to overcome the somatic resistance. Towards the action of filth products, however, it seems that the human organism is capable of acquiring tolerance ; and thereby it becomes less liable to enteric fever. It is possible, therefore, that modern sanitation, while diminishing the chances of exposure to the bacillus and to the filth products that favour its action, increases the susceptibility of man. Thus, the English soldier is tolerably safe in England, without the aid of filth-tolerance ; but when he is transferred to a land of insanitation like India, his want of filth-tolerance tells against him. It may even be feared that the comparative purity of cantonments in India, like the comparative purity of the land he has come from, may make the British soldier more prone to infection in the dirty bazaars. It has been said that enteric fever is the disease which shows most the influence of sanitary improvements ; and no doubt it may be so when the improvement is widespread over the country ; but in India the Europeans who live in clean cantonments and civil lines cannot, or do not, keep themselves quite unspotted from the primitive filth of the great mass of the country. This surrounding filth is ever ready to encroach on any cantonment where there is the slightest laxity of sanitary supervision, and is a standing danger to individuals. Since efforts to banish enteric fever by purifying the water-supply have met with so much less success than was expected, medical officers, aided by the visits of special sanitary officers, have been forced

to turn their attention to the details of the sanitary condition of their stations. Some sanitary transgressions and omissions are found in the lines, but more in the bazaars ; and it may here be noticed that in France the measure which in India is called "putting the bazaar out of bounds" is said to have met with some success in checking the disease.

Boobbyer of Nottingham's experience is that the disease is endemic in poor overcrowded localities, irrespective of geological formation, provided that soil-pollution and like favourable conditions are present, and that, under equally unfavourable circumstances, the better class of houses has fewer cases than the poorer. This latter point is explained by some as the result of sick-room infection in small overcrowded houses. Sir Charles Cameron's observations on the greater incidence in Dublin of enteric fever on the gravel soil than on the clay, and the supposed explanation, are noticed in the Army Medical Report for 1897. His views have been disputed.

Auto-Infection.—In the narration of their investigations into the Belfast epidemic, Lorrain Smith and Tennant have occasion to refer to the experimental results obtained by Sanarelli, some account of which will be found in the report for 1894, paragraphs 14 and 52, pages 25 and 69. The two results of Sanarelli's work, they say, which have a direct bearing on their own investigations are (1) the effect of coli products in increasing the virulence of the typhoid bacillus, and (2) the effect of the injection of typhoid toxin in bringing about an invasion by the colon bacillus ; Sanarelli thinking it probable that auto-intoxication with products of intestinal fermentation is a factor in the causation of typhoid fever—a suggestion which brings the theory of the disease into line with his experimental results. Their object in the investigation was to show that in patients there can be obtained from the serum indications of colon bacillus invasion during the process of typhoid fever ; and there is a large body of evidence to prove that Sanarelli's experimental results are directly applicable to typhoid disease in the human subject. The supposed danger seems to be that a poisoning from the intestine or a change in the condition of the intestinal flora may make a man fall an easier victim to the enteric bacillus, if the latter enters at the proper moment. Another view is that the *bacillus coli* under certain unknown conditions becomes changed into the enteric bacillus. A third is that enteric fever is not a unity, but a congeries of symptoms which may be caused now by the enteric bacillus, now by the *bacillus coli*, now by the bacillus of Gaertner, etc. D. B. Spencer wishes to distinguish between true enteric fever, due to the ingestion of sewage matter from outside the body, and fermentation fever, of which "tropical enteric fever" is a form due to sewage matter belonging to the body.

Origin-tracing.—It is not only in India that difficulty is found in tracing the actual channel of infection in a given outbreak. Both Peck of Chesterfield and Mair of Gainsborough learned by experience that, while it is frequently easy to find a number of possible causes, it is hardly ever easy to fix upon one undoubted cause, and sometimes impossible even to guess one ; and Mair was able to trace origin from a previous case only in 31 per cent. of attacks.

Weather and Season.—Berger, for a locality in Germany, found that enteric fever was most prevalent in August and least so in November-February ; that it was at its height when temperature, humidity, and dew-point rose ; taking only pressure and temperature, that it rose when pressure fell and temperature rose ; taking pressure, temperature and humidity, that it was at its highest when pressure, temperature, and humidity rose, and at its lowest when pressure rose with temperature and humidity falling, or when humidity rose with barometer and temperature falling. Similar detailed observations are wanting for India. In England it is said that a high (over 55° F.) sustained summer temperature is followed by a high autumnal prevalence, and a cool summer by a low autumnal prevalence, and that enteric fever and diarrhœa are therefore parallel in their relations to temperature.

Hardiness.—It has already been mentioned that the enteric bacillus has been recovered from unsterilized soil 50 days after inoculation into it. Klein found that in the period between 15 and 20 days the enteric bacillus had died out in buried bodies of guinea-pigs ; Pfuhl, that the enteric bacillus can flourish on boiled potato and grow into its substance even in the presence of the colon bacillus or the bacilli of garden earth ; Sitsen, that drying produces first increased resistance against carbolic acid, and ultimately diminished resistance. A very general statement of Ficker's results is that thin layers of old, not very virulent, cultures are more easily killed by drying than cultures of opposite characters, and the higher the temperature the more easily ; that alterations of dryness and moisture are very fatal ; and that moist heat kills more quickly young cultures than old. It has already been mentioned that the enteric bacillus can be killed in water by shaking.

Friends and Enemies. Mixed Infection.—Both Lorrain Smith and Houston agree with Sanarelli that symbiosis with the enteric bacillus increases the virulence of the colon bacillus, and that, on the other hand, the *bacillus coli* may be directly concerned in the production of a virulent enteric infection. In his experiments Sanarelli had found that the bacillus of Escherich produces increase of virulence of the bacillus of Eberth, and that the injection of enteric toxin favours invasion by the *bacillus coli*. It is said also that the staphylococcus is inimical to the enteric bacillus, while the streptococcus is helpful to it. Attempts have been made by means of the Gruber-Widal reaction to diagnose mixed infections, and it has been suggested that not only the colon bacillus but also the bacillus of Gaertner, and perhaps other bacilli, may occur in mixed infection with the enteric. Thus, Biberstein found that in 15 out of 18 cases enteric patients' serum agglutinated the colon bacillus more than the normal serum did, and sometimes agglutinated the colon bacillus more than the enteric ; the inference being that in these cases the patient was invaded both by the bacillus of Eberth and by that of Escherich. Evidence of the existence of mixed infection by the same two bacilli was obtained in Belfast, as already noted, by Lorrain Smith.

Susceptibility.—It is supposed that "enteric families" exist, families that are more liable than others to be attacked by enteric fever, either from a general susceptibility of body or from an idiosyncratic constitution of the intestinal flora. So, too, there is some evidence of the existence of "enteric houses," houses which have been repeatedly invaded in different years ; but it is to be presumed that it is only change of tenants which directs attention to such houses, because, as a rule, constant dwellers in insanitary surroundings seem to acquire a certain amount of tolerance of the enteric virus, though new comers are very apt to suffer. Whitelegge has noticed that such acclimatized persons are apt to get enteric fever after they have been away on a visit to the sea-side, having lost their immunity by the change of residence. But in the short report of his remarks the proof is not given that the infection was not contracted at the sea-side. The opinion of the medical officer of Ahmednagar, quoted in paragraph 16, page 29, of the report for 1897, may be referred to. It is probable that the enteric bacillus, like other pathogenic microbes, can only attack the enfeebled ; but it is not quite clear whether general enfeeblement is enough, or whether a particular kind of enfeeblement is necessary. Children also are liable to the disease, but the younger the child the less the march of the attack is like that seen in the adult. The evidence regarding a possible greater liability of total abstainers is very imperfect ; but even if the greater liability were proved, it would be an argument not against total abstention but for the purification of water-supplies. The question is chiefly interesting in that some look to a greater liability of abstainers as a proof of water-conveyance.

Cycles and change of Type.—If there is any truth in the idea mooted in England that the lessened prevalence and mortality from enteric fever, said to be attended by some change of type in symptoms and lesions, is at least partly due, not to sanitary improvement, but to a cyclical diminution of infectivity, India may be in a cycle of increase.

Enteric-like Fevers. Typho-malarial Fevers. Diagnosis.—It is well known that there are some who hold that the so-called enteric fever met with in India, or at least the bulk of it, is not the same as the enteric fever of Europe, and D. B. Spencer has lately asserted that true enteric fever is rare in India. The great body of opinion, and the results of bacteriological investigation, so far as they have gone, are, however, in favour of the view that the enteric fever of India is the same as that of Europe, though there may in India, as in Europe, occur cases of enteric-like fever caused by other and related bacilli. The colon bacillus, which has a bad record as a cause or accomplice in many diseased conditions, is most frequently blamed for these enteric-like fevers, though the *bacillus enteritidis sporogenes* (Gaertner) has also been accused in such cases. Gwyn in a case which was clinically typical found a paracolon bacillus which had characters of both the enteric bacillus and the colon bacillus. It is possible that in such cases the bacillus met with was the *bacillus faecalis alkaligenes*, which is said to be nearer the enteric bacillus than the colon bacillus is. The evidence available goes to show that there is no separate fever to be called "typho-malarial," cases so designated being mixed infections by the malarial animalcule and the enteric bacillus. At least 31 cases have been published (29 by Lyon, 1 by Wilson, 1 by Goltman) in which both parasites were found to be present by bacteriological and microscopical methods. Cases have been published of sudden influenza passing ultimately into enteric fever immediately after an epidemic of influenza, and of confusion of diagnosis between the two at the beginning of an outbreak (Clifton). Difficulty of diagnosis also arises with tubercle, simple continued fever, plague, etc.

Enteric Fever a Blood Disease. The Bacillus in the Blood. The Bacillus in Sputum and Sweat.—In reporting a case of cystitis caused by the enteric bacillus, which remained localised in the bladder though it communicated to the blood the power of agglutination, Houston concludes that the fact that the enteric bacillus can grow in the tissues without any symptoms of enteric fever resulting, and produce there a local lesion, is in favour of the view that this fever is a true general infection, and not merely of local origin in the Peyer's patches of the intestine. Experiment seems to show that the intestinal bacteria cannot get through the healthy intestinal wall. Sudakoff found the enteric bacillus in the blood in one case, in the blood and sweat in one case, and in the sweat in one case. The blood from the roseola from 14 cases was examined by Neufeld by a new method, of which rapid work, so as to avoid the bactericidal action of the blood, and the use of a fluid medium, were the chief features; and from only one did he fail to cultivate the bacillus, and that case was also refractory to the Widal and other bacteriological tests. Richardson found the bacillus in the sputum of a case with pneumonia on three successive days; but he failed to find it in 15 cases where there was no pneumonia.

Enteric Fever without intestinal lesions.—Cases of enteric fever without intestinal lesions continue to be reported; but a certain amount of doubt rests upon many of them on account of the insufficient proof offered that the bacillus found in the organs was really the enteric bacillus. However, some cases have been properly authenticated. It has been suggested that enteric fever without lesions is more frequent now than formerly, on account of a change of type in the disease, the brunt of which tends to fall on other systems or parts of the body rather than on the intestinal. If this be the case, enteric fever must, as Sanarelli contends, be a blood disease with a secondary intestinal infection, and not an intestinal disease with a secondary blood-infection. It was mentioned in last report that some of these cases are supposed to be caused by the bacillus of Gaertner.

The Bacillus in the Organs, and its presence for long periods.—The enteric bacillus can often be found in the gall-bladder when it is no longer present in the stools, and it may there be in pure culture. The gall-bladder may itself be affected with inflammation, ulceration, or perforation, and the presence therein of attenuated enteric or colon baccilli sometimes leads to the formation of gall-stones. It is stated that the enteric baccillus has been found in pure culture in suppurative lesions in the ribs, clavicle, radius, ulna, femur, tibia, and the bones of the fingers and toes; in the blood, the heart muscle, the endocardium, the arteries and veins of the legs; in the muscles of the neck, shoulder, abdominal wall, and legs; in the peritoneal cavity, the spleen, the liver, the bile, the kidney, the urine, and the mesenteric glands; in the brain, the parotid gland, the thyroid gland; in the lungs and the pleura; in the ovary; in the testicle. The cases of mixed infection are equally numerous and widespread. It has sometimes been found in the bone-marrow, even in cases that gave no Widal reaction, also in cases of abscess of the connective tissue, periostitis, osteomyelitis, empyema, pleurisy, in typhoid lesions of the larynx, in otitis media, in diseases of the testicle and thyroid gland; in ulcers of the vulva and vagina, and in abscesses of the glands of Bartholin. Cases in which the enteric bacillus has been found in pure culture in the body up to 8 or even 15 years are quoted from von Dungern, Buschke, Bruni, Sultan, Chantemesse, Houston, and others. References on this subject were also given in the report for 1897.

Experiments on Animals.—Chantemesse reports having given a monkey enteric fever by feeding it with small quantities of bacilli for three or four days. It died on the twelfth day, and there were found ulcers in the large intestine and caecum and swelling of the mesenteric glands and spleen. In sections of the spleen there were numerous enteric bacilli. Row successfully exalted the virulence of cultures by passage, the animals used being guinea-pigs.

Prevention. Inoculation.—To kill or intercept the microbe and to increase the resisting power of men are the two methods of prevention; and general measures of sanitation are believed to act in both ways, because the purer the surroundings the more healthy the human individual will be, and the less likely to meet with noxious germs. But there is some suspicion, as has already been mentioned, that purity of surroundings may actually make men more susceptible to corporeal depression by a subsequently experienced impurity of environment, and therefore more apt to fall victims to the virus of enteric fever. Sanitary purity would be more effectual if it were general, but in India at present it can only be partial. It is known that the soldier in his clean lines and barracks is closely surrounded by the pollutions of the bazaar, and the enteric bacillus is widely

distributed. Therefore recourse to the inoculation methods of Wright is by many strongly advocated.* Haffkine thus concludes a lecture of argument delivered before the Royal Society :—

From the point of view of preventive measures, in diseases like rabies, or syphilis, or small-pox, or leprosy, where infection can be found in the patient alone, precautions of isolation taken with regard to the sick and their closest surroundings must affect directly the prevalence and propagation of the disease ; whereas in typhoid fever, or cholera, or plague, where the patient is only one, and proportionately a limited source of danger, his isolation, and the destruction of his belongings, leave unaffected the vast cultivations of infection which are going on in nature besides ; and measures taken for circumscribing the prevalence of the epidemic by isolating and destroying the foci of infection are less likely to succeed in this category of diseases. Attempts to eradicate an epidemic or to protect individuals by means which succeed in merely contagious diseases will in this case easily be eluded, and the necessity of personal protection by means of prophylactic treatment will be soon urgently felt and acknowledged.

Opinions of Medical Officers.—In but few cases is it stated that particular regiments or barracks were especially attacked. As usual, the most salient factor in such cases was recent arrival in India of the regiment, or of drafts, coupled with youthfulness of the men, greater nearness to bazaars, or greater exposure to infection-laden wind being among the contributory causes adduced. In some cases no explanation is attempted. At least two men, and perhaps three, appear to have already contracted the infection before they landed in India, while two or three are said to have been infected at Bombay, or *en route* therefrom. Medical officers frequently noted, especially in the case of hill stations, that the disease must have been contracted before arrival, either from impurities encountered on the march, or from a cause existing in the previous station ; so that the station where the disease was treated was not always the station in which it was contracted. Into Shahjahanpur two cases were imported, it is said, and the disease then quickly spread. The danger of ambulant cases is also noticed in some reports. The evil effect upon individuals or upon regiments of active service on or beyond the North-West Frontier was observed in several stations. One medical officer expresses the opinion that the so-called enteric fever of India is climatic in origin, and that ague is a principal factor in its causation ; while another considers that ague acts indirectly by deranging the safeguarding function of the liver. Typical *post-mortem* appearances were noted at Cherat and Bangalore, and the medical officer of the former station believes that the enteric fever of India is not the same as that of England. A belief is expressed by the medical officer of Nasirabad that enteric fever in India may be caused by microbes other than that of Eberth, by the *bacillus coli* for example. Some patients acknowledged having drunk foul or doubtful water in the bazaar, or when out shooting, or on the march, or on the rifle-range, or when rambling about the khuds. The bazaar is, as usual, considered by many medical officers as the place where enteric fever is mostly contracted, by the partaking of aërated waters, ice-cream, fruit, cakes ; suppers in shops, eatinghouses, or brothels. The medical officer of Nasirabad mentions that urine and even fæces have been found in the so-called drinking water standing ready in a brothel. At Poona seven of the attacks were among men who were constantly about the bazaars on plague duty. In the experience of Umballa and Poona, placing the bazaar out of bounds had a good effect. At Calcutta a milkman was detected washing his cans with dirty water ; at Jutogh a bhisti was seen filling his mussack from a dirty pond, and it was discovered that the galvanised iron tanks were being cleaned with the aid of mud ; and at Peshawar it was found that the water-pipes in their course sometimes passed through foul irrigation channels. With regard to Shahjahanpur it is stated that mussacks were used, that the wells were not protected with permanganate of potassium, that the latrine arrangements were bad, that there were no chicks to the kitchens, and that when these defects were remedied the epidemic ceased. It is said that after the wells at Roorkee were put in good order and the water-barrels cleaned, there were no more cases of enteric fever. At some other stations mussacks, pakhals, and motes were still in use, with unprotected wells. At Jullundur the distribution of the drinking water, and at Aden the distribution and storage of the same, and the disposal of the waste water, were reported to be faulty ; and liability to contamination is asserted with regard to the water-supply of Umballa, Bellary, Meiktila, Mandalay, Poona, Nasirabad, and Deolali. At Poona variation of water-head pressure was supposed to induce suction of external, and perhaps foul, moisture into faultily joined or damaged pipes. A multiple water-supply, always a dangerous arrangement, was reported as existing at Calcutta, Ranikhet,

* A certain amount of inoculation work has actually been carried out, but no reports on the subject have yet been received.

Fort Lahore, Fort Attock, Thobba, Murree, Madras, Secunderabad, Rangoon, Shwebo, Purandhar, Nasirabad, Neemuch, Taragarh, and Aden. The municipal water was suspected in the case of Cawnpore and Agra, though the civil population did not suffer to the same extent as the military. At Agra the enteric bacillus was reported present in the water of No. 4 well, and on three occasions in the municipal water ; and at Mhow a bacillus resembling that of Eberth was found in the lake-water. The enteric bacillus having been found in the water of a camp well at Meerut, the regiment moved away, with good effect. At Bangalore the medical officer noticed that most cases were occurring in bungalows on low ground and near the horse-lines, but this incidence was, in his opinion, afterwards explained by the finding of the enteric bacillus in some drinking water placed near the horse-lines for the use of the men. The result of bacteriological examination in the case of Jubbulpore, Sitapur, Fatehgarh, Ranikhet, Bellary, Nasirabad, and Mount Abu was negative. At some stations the water was regarded as excluded from the possible vehicles of infection, because the outbreak was not widespread ; while the medical officer of Chakrata points out that enteric fever was less prevalent there at a time when the *bacillus typhi abdominalis* was reported present in the water than it is now when the water is reported pure. At Quetta the water-supply was insufficient. The arrangements for the manufacture and supply of aërated waters was here and there unsatisfactory, but no cases of enteric fever were traced to this condition of things. The combined results of five stations was that 116 cases occurred among total abstainers, and 396 in non-abstainers, or 23 and 77 per cent. respectively. But, as their average annual strength cannot be obtained, no conclusion can be drawn as to the relative liability of those two classes. That there was no observable difference of liability was the belief of the medical officers of Rawalpindi and Bangalore. At Kasauli and Poona the medical officers were not satisfied with the dairy arrangements. In certain stations the immunity, or comparative immunity, of women and children was used, as in previous years, as an argument against the probability of the spread of the disease by means of milk, whereas in others the fact that women and children suffered was held to throw suspicion upon the milk or upon something affecting women and children as well as men, such as air-borne fæcal dust. The fact that attention to dairies and milk-supply had produced no effect on the annual amount of enteric fever was also advanced as a proof that milk had not been a vehicle. There was an impression at Jubbulpore that the subsoil water had risen of late years owing to the new water-supply and the disuse of the wells ; and the medical officer of Ranikhet says that there has been more enteric fever at Lucknow since wells were disused and the Gumti water taken into use, the circulation of the ground water having been choked. At Jhansi, on the other hand, the prevalence of enteric fever was attributed to the very low level of the subsoil water and the considerable drying up of the wells, the result of a three years' drought. Unlike Jubbulpore and Lucknow, however, Jhansi had a lower enteric fever admission ratio in 1898 than in 1897. The question of the conveyance of the infection in dust-laden wind has again attained some prominence in 1898. The infective dust is supposed to enter into the mouths of the men, to fall into the water, and to settle upon the food. Along with dust, flies are mentioned as likely carriers of infection from fæces to food. Some medical officers, therefore, dwell on the importance of protecting the kitchens from dust and flies, of excluding from them all natives except the actual cooks, and of closely supervising the cleanliness and personal habits of the cooks, who are often sweepers, or little better. For some regiments stringent detailed rules as to the management of the cookhouses were issued under the authority of the officer commanding. One reform suggested from various sides is that the men should be made to cook for themselves without the aid of natives, and this has actually been carried out by the Gordon Highlanders. The conveyance of infection by means of air-borne dust, if a reality, must be confined to the dry seasons, and dust-storms are most frequent in the dry hot season ; but a second maximum of the disease in the damp months of August and September is very usual ; and the medical officer at Rangoon remarks that cases generally begin to come in after the first rain. Exposure to the sun and fatigue from work at the rifle range, from military training, from football training, or from other exertion are mentioned in some reports as contributory causes. The danger in badly managed mortuaries from the careless spreading abroad of undisinfected intestinal contents, a danger brought to notice by V. Poore, is again this year referred to. The medical officer at Cherat stated that some of the bungalow sites and tent-sites were unhealthy, the lower on the hill the more unhealthy ; that there was a want of personal cleanliness, that there was a difficulty in ventilating tents, and that no cases could be traced to dirty native cooks or dirty tanks. Bernardmyo, which was first occupied in 1888, is said never to have *originated* a case of enteric fever. Fatehgarh had none during the year. The disease is said to be rare at

Calcutta, Pachmarhi, Roorkee, Mandalay, and Colaba. As to Roorkee, the reason given is that it is a small, clean station, to which young drafts do not come. The immunity of Mandalay is said to be in spite of a water supply very liable to contamination. The Dagshai Military Prison was always free from enteric fever, even before resort was had to boiling and permanganating the water; in 1896 the water contained the enteric bacillus, but no men got the disease; and in 1897 the medical officer's family partook of lemonade containing the bacillus, but all escaped. Meiktila is said to have had no enteric fever since 1895, the water having been boiled since April, 1896; and it is stated that Neemuch has had no cases that could be attributed to the station since the new water supply was introduced. The reduction in Kurrachee was supposed to be due to attention to all points of sanitation. At Meerut removal from the neighbourhood of a well containing the enteric bacillus was apparently successful in staying an outbreak; and good results were reported to have been obtained at Umballa and Poona by placing the bazaars out of bounds. On account of the persistent occurrence of enteric fever there, Dagshai was totally evacuated early in 1898, and remained unoccupied until April, 1899. A great deal of attention seems to have been devoted to the purification of the drinking water, a good deal to that of the aërated waters, and some to that of the milk. In some stations the wells were cleaned out once or twice a year, and were treated once a week with potassium permanganate. Boiling and the addition of potassium permanganate were very extensively used for the purification of the drinking water, the boiling being carried out in at least seven stations in Larymore patent boilers. In half a dozen stations alum was used. The men at Calicut are said to have drunk only aërated waters, because they did not like the permanganated water. A good deal appears to have been done in the matter of substituting galvanized iron vessels for leather ones. At Agra the water of a well in which the enteric microbe had been detected was treated with hydrochloric acid and potassium permanganate, and was examined bacteriologically once a week. The officer commanding at Sitapur issued detailed instructions regarding the care and purification of the wells and drinking water. At some of the stations in the Murree Hills the water was so pure that sterilization was not required, and that process was only resorted to when drought necessitated recourse to a second source of supply. Some regiments introduced filtration, permanganation, or boiling, as purificatory processes, into their aërated water factories, and used only permanganated water for washing the bottles. At Amritsar there are said to be no aërated waters sold in the bazaar except those of barrack manufacture. Precautions as to milk are usually mentioned, if at all, in general terms. The special measures noticed are milking in presence of a European, sending the milk out in locked cans, and boiling. At some stations incineration was resorted to for the destruction of infectious stools only, while in others an attempt was made to dispose of all nightsoil and rubbish by that method. The efficiency of the different incinerators employed was variously estimated. Reviewing the reports received on this point, His Excellency the Commander-in-Chief in India states that no thoroughly satisfactory incinerator has yet come under notice; that the incineration method must still be considered as being in the experimental stage; that experiments will be continued; and that a trial is being given at Cawnpore to an apparatus intended by its designer to consume both liquids and solids. The clothing worn by men suffering from enteric fever, venereal disease, and other infectious maladies, was boiled before being handed over to the washermen. Out of the 2,498 cases of enteric fever which occurred throughout the army of India in 1898, 37 are noticed as having declared themselves among patients in hospital or among attendants. Out of these about 11 were in hospital for early venereal disease, and about 8 for other diseases; and 18 were attendants on enteric fever cases. The number of attendants attacked was, as in the previous year, high. A second attack was the lot of a man at St. Thomas' Mount, whose first attack had been at Secunderabad in the previous year. Cases in which enteric fever and dysentery were more or less closely connected were observed at Calcutta, Barrackpore, and Quetta; but at Quetta this connexion was not so frequent as in the preceding year. A case each of enteric fever at Fyzabad, Cawnpore, and Umballa was complicated with multiple abscess of the liver, that lesion in the Fyzabad case being part of a general pyæmia; while in three cases of abscess of the liver, which occurred respectively at Lucknow, Agra, and Shwebo, the origin of the abscesses was stated to have been the intestinal ulceration of enteric fever. In a case of single abscess of the liver occurring at Lundi Kotal, the length of time that had elapsed since the close of the attack of enteric fever rendered the reality of the connexion somewhat doubtful.

Medical officers reported on outbreaks the causation of which was believed to have been discovered, or in the case of which the drinking water was suspected, or was said to contain the enteric bacillus; of the measures considered to have been effectual in preventing

or checking the disease; and especially of the results obtained by boiling the drinking water, or by adding to it potassium permanganate or other chemicals. Though 1898 was the third year in which those methods of water purification were officially in force, it will be seen from the following table that the amount of enteric fever in India still continued to increase. It is scarcely to be believed that the measures in question were everywhere so carelessly carried out as to be worse than useless, and the suspicion arises that in applying them to the water supply the authorities were not applying them to the real origin of the disease. This point was more fully dwelt upon in the report for 1897.

Commands.	Year.	Enteric Fever.		
		Admissions.	Ratio per 1,000 of strength.	Difference.
Bengal	1897	786	39·1	+ 2·0
	1898	824	41·1	
Punjab	1897	724	42·1	+ 6·6
	1898	895	48·7	
Madras	1897	237	19·2	− 7·6
	1898	143	11·6	
Bombay	1897	303	20·4	+ 14·7
	1898	513	35·1	
India	1897	2,214	32·4	+ 4·5
	1898	2,498	36·9	

No explanation can be offered as to the reduction in Madras and the rise in Bombay. The chief reductions in the Madras Command were at Rangoon, Secunderabad, Calicut, Mallapuram, and Pallavaram, though eight other stations had also lowered ratios. The chief rises in the Bombay Command were at Quetta, Kirkee, and Taragarh, though six other stations shared in the rise. Of the seven stations which *reported* the use of Larymore boilers for the sterilization of drinking water, Dinapore, Nasirabad, Neemuch, Indore and Mhow had admission ratios lower than those of their geographical groups, and Dinapore, Meerut, Indore, and Neemuch, admission ratios lower than those of their commands; while Meerut and Muttra had ratios higher than those of their geographical groups, and Muttra, Nasirabad, and Mhow, ratios higher than those of their commands.

Enteric Fever in 1898.—There was again an increase of both morbidity and mortality from enteric fever in 1898. The admission ratio rose from 32·4 to 36·9, and the death ratio from 9·01 to 10·17, a difference of 4·5 and 1·16, respectively. There were 2,498 admissions and 689 deaths, against 2,214 and 616 in 1897. The average number of men constantly sick* from enteric fever was 321, and the average duration of a case* was 56 days. The total loss of service* due to the disease was about 117,023 days. At Rawalpindi, Bangalore, Ahmednagar, and Quetta, Widal's test was employed as a means of diagnosis, 82 times at Quetta.

Fever Mortality.—The following table shows an increase in total fever mortality, which may with some reason be ascribed to the greater youthfulness and less average length of service of the soldiers of to-day :—

	1870–79.			1881–90.†			1897.			1898.		
	Enteric fever.	Other fevers.*	Total of both.	Enteric fever.	Other fevers.*	Total of both.	Enteric fever.	Other fevers.*	Total of both.	Enteric fever.	Other fevers.*	Total of both.
Army of India	2·03	1·42	3·45	3·79	·70	4·49	9·01	1·02	10·03	10·17	·73	10·90

* Intermittent, remittent, and simple continued fevers.
† Excluding troops on active service in Burma during 1885 to 1887.

It is a well-known fact, and it may be seen in various tables of this report, that malarial is much less fatal than enteric fever. The liability to die of malarial fever is

* Excluding field forces, Malakand Force, and Kyber Force and Brigade.

greatest after 30 years of age, while the liability to die of enteric fever is greatest before 25. The British Army in India is at present a youthful army, with 90 per cent. of the men under 30 years of age, whereas the corresponding percentage in 1871—79 was only 67.* Similar results are arrived at with regard to length of residence in India. Therefore, the explanation offered above of the facts displayed in the table just given appears to be correct.

The following table shows enteric fever in the geographical groups in the decennium 1886—95 and in the last two years :—

Admissions per 1,000.

Period.	Burma Coast and Bay Islands.	Burma Inland.	Bengal and Orissa.	Gangetic Plain and Chutia Nagpur.	Upper Sub-Himalayan.	North-Western Frontier, Indus Valley, and North-Western Rajputana.	South-Eastern Rajputana, Central India, and Gujarat.	Deccan.	Western Coast.	Southern India.	Hill Stations.	Hill Convalescent Depôts and Sanitaria.
	I.	II.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII*a*.	XII*b*.
1886–95 ...	5·7	5·5	7·7	27·7	25·4	15·6	23·9	17·0	5·8	12·1	25·1	13·9
1897	20·8	1·1	11·0	36·9	33·5	22·3	63·7	24·3	10·2	26·8	49·7	14·9
1898	7·3	4·5	19·3	44·1	36·6	29·6	47·1	25·7	2·6	19·3	59·7	20·3

It shows that Groups V, VI, VIII, and XII*a*, especially, are apt to have high ratios of admission from enteric fever; and Groups II and X, and, to a less extent, I and IV, low ratios. It also shows at a glance how the groups compare with each other in 1898, and how 1898 compares with 1897, or with the decennium. Group XII*a*, Hill Stations, had the highest ratio of 1898, and Group VIII, followed by Group V, the next highest; and in the same three groups also, but in the order XII*a*, V, VIII, the percentage of enteric fever in total admissions was greatest. The table also shows that, whereas in ten groups the ratios of both 1897 and 1898 were higher than the corresponding ratios of the decennium, only in Burma Inland were the ratios of both years lower than the decennial ratios. Moreover, in seven groups the 1898 ratios were greater than the corresponding ratios of both the preceding year and the decennium; while only in Western Coast was the 1898 ratio less than both.

As regards enteric fever in stations, the following table shows those garrisons which had an average strength of over 1,000 in 1898, with the decennial ratios for reference :—

Stations.	1898.		Decennium, 1886–95.	
	Admission-rate.	Death-rate.	Admission-rate.	Death-rate.
Quetta	108·5	35·08	15·0	3·15
Lucknow	74·1	22·57	37·3	7·07
Agra	73·5	16·71	24·0	7·66
Peshawar	52·0	24·48	18·7	7·88
Rawalpindi	51·8	10·95	24·5	6·85
Mhow	45·6	12·01	27·5	6·78
Allahabad†	43·6	16·03	24·2	4·84
Meerut	40·0	9·74	26·8	7·83
Umballa	35·3	13·19	21·7	5·41
Bangalore	30·3	4·26	16·0	3·47
Poona	24·2	4·73	15·4	5·06
Bareilly	20·9	5·44	39·8	9·41
Sialkot	17·7	8·45	38·8	8·89
Secunderabad ...	17·4	4·70	23·7	6·04
Fort William (Calcutta)	13·3	·89	4·3	2·13
Wellington	12·4	2·85	7·5	2·46
Aden	10·8	4·93	3·5	1·81
Rangoon	8·3	·92	5·4	2·55
Kurrachee	6·8	3·89	13·8	3·07
Colaba (Bombay) ...	2·5	·83	4·9	1·83
Belgam	1·9	97	2·2	·49

* Bryden and Stephen, Tables for 1870—79.

† Including Fort Allahabad.

The high position occupied by the decennial admission ratios of Bareilly, Sialkot, and Lucknow will be observed, and the low position of the ratios of Belgam, Aden, Calcutta, Bombay, and Rangoon. The enormously high 1898 ratio of Quetta is also striking, and the contrast which it presents to the ratios of Belgam, Colaba, &c., at the bottom of the 1898 list, as well as to its own corresponding decennial ratio.

In regiments the admission and death rates were highest in the cavalry; there was no enteric fever among the engineers, who are men of greater average age and service, and mostly married; and, next to them, the artillery suffered least. These results are the same as in 1897. The regiments which had an admission rate over 100 per 1,000 and a death rate over 40 per 1,000 were the 2nd Battalion of the Oxfordshire Light Infantry at Lundi Kotal, and the 1st Battalion of the Wiltshire Regiment at Quetta. The former returned from field service on the 9th April, and the latter was at Kurrachee the first three months of the year; and the former received 249 and the latter 200 men from England during the year.

With regard to the relation of mortality from enteric fever to age and length of residence in India, the general results confirm those of former years. The ratio of mortality from enteric fever per 1,000 of strength was greatest in the age period 20—25, and the relative liability of the same period was 44 per cent. In the same age-period the total number of deaths from enteric fever was 428, and out of 100 deaths from all causes 61 were from enteric fever. Lastly, out of the total number that died at all ages from enteric fever 74 per cent. were between 20 and 25 years of age. Again, the ratio of mortality from enteric fever per 1,000 of strength was highest in the first year of residence, and the liability in the same year was 38 per cent. In the first year the total number of deaths from enteric fever was 236, and 70 out of every hundred deaths from all causes were from enteric fever. Lastly, out of the total number that died at all periods of residence from enteric fever, 41 per cent. were in the first year of Indian residence.

The age period 20—25 included 51 per cent. of the total strength of the Army, and in the same period the liability to fall sick of enteric fever was greatest, 46 per cent. In the succeeding periods the liability rapidly declined. Again, though 18 per cent. of the men of the Army were of less than one year's service in India, 18 per cent. of more than 1 and less than 2, and 18 per cent. of more than 2 and less than 3, yet the liabilities of the men of these three equal percentages to contract enteric fever were respectively 43, 18, and 12. The greater has become the supply of susceptible material, the more enteric fever has prevailed.

In the period 1886–95 as a whole the chief enteric fever season, though the disease occurred in all months, was the six months April—September, with one maximum in May and another in August; and in 1898 the distribution was the same :—

YEARS.*	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.	Ratio per 1,000.
1886–95	518	418	689	1,427	1,795	1,365	1,441	1,718	1,400	923	745	879	13,318	19·6
1898 ...	201	165	164	332	400	219	197	238	163	124	171	124	2,498	36·9

* The warning given at the end of the table of contents of the Annual Returns as to the months not being calendar months applies here also.

In 1898 the greatest prevalence of enteric fever was in April and May, and again in August; of simple continued fever in May and June, and again in August; of remittent fever in May, and again in July and August, an abnormal distribution which has already been noticed. Of the larger groups Gangetic Plain had maxima in January, March, April, August, and November; Indus Valley in January, April, and November; Deccan in April, August, and November; Central India in April and September; Hill Stations in May and August; and Upper Sub-Himalaya in May and December.

Plague.—In the European army of India there occurred 9 cases of plague, with 2 deaths, against 5 without death in the previous year :—

	Admissions.	Deaths.
Bombay (Colaba)	3	1*
Poona	2	0
Bangalore	2	1
Nasirabad	1	0
	8	2

* Out of hospital : 8 *plus* 1 = 9 *cases.*

All the men attacked at Colaba had been on plague duty. The fourth man affected died before arrival at the hospital. "It is believed that the virus obtained entrance to his system through a small chafe near the ankle. This became intensely painful, and, high fever with delirium occurring at the same time, death took place within a few hours of the invasion of the disease." At Poona two men of the 2nd Battalion of the Royal Irish Rifles were admitted, the bacillus being recognized in one. One of these men had been inoculated against plague in April, and contracted it in January. Fifty men of the garrison had been inoculated at the same time. Both the men had been employed in the city on plague duty, where they contracted venereal, and were both in hospital when their symptoms of plague appeared. The case at Nasirabad was in the person of a soldier of the 27th Field Battery, Royal Artillery, who had just arrived from England. He was detained in Bombay for some time before proceeding up-country, and when he arrived at Nasirabad it was found that he was suffering from plague. The patient recovered, and the disease did not spread.

Tubercle of the Lungs.—The admission-rate from tubercle of the lungs fell, while the death-rate was slightly raised. Contrary to the experience of the past two years the Bombay Command and the Gangetic Plain group had the highest admission ratios. The medical officer at Dinapore notes the share of syphilis in predisposing to vulnerability, and the medical officer at St. Thomas' Mount the influence of exposure during field service. Several officers mention the fact that a case of tubercle of the lungs is apt to yield more than one admission. In the reports from the stations where ratios were highest there are no further remarks of interest or importance. Ten cases, without death, of non-tubercular phthisis were returned.

Only for the two years 1897–98 can European and Native troops be compared with exactness in the matter of tubercle of the lungs, and the following table shows the comparison for India and for each group :—

1897–98.

Groups.	Tubercle of the Lungs.				All Tubercular Diseases.		
	Admissions.		Ratio per 1,000.		Troops and Prisoners.	Admissions.	Ratio per 1,000.
	European Troops.	Native Troops.	European Troops.	Native Troops.

India	486	771	3·6	3·0			

* No Troops.

Much of the tubercle of the European troops is no doubt contracted in England. Accordingly, death from tubercle of the lungs is proportionately highest at the beginning and end of service, and at the earlier and later ages, while invaliding from it is most common in the intermediate period. With regard to Native troops, it must be remembered that Gurkhas, and perhaps Dogras, have high ratios, so that race, as well as location, has

to be considered. For example, Gurkhas preponderate in the garrisons of the Hills and Assam. High ratios have prevailed among the European troops of the Deccan for some years past, and the explanations offered were not satisfactory. However, there is a great improvement in 1898. Speaking generally, it may be said that in the more northerly parts of India the Native troops, in the more southerly the European troops, suffered more. The ratios from all forms of tubercular disease taken together were highest in prisoners, and next in European women, and the same had the highest and next highest ratios from tubercle of the lungs. The highest ratios for tubercle of the brain and its membranes, for tubercle in the abdomen, for tubercle of the lymph glands, and for tubercle of the bones and joints, were those of the children, prisoners coming second in the case of abdominal tubercle.

Flügge and his pupils have shown by experiment that the fine spray ejected from the mouth of a tuberculous patient in coughing may contain the tubercle bacillus, and is therefore a source of danger to others, a danger which may be averted by the polite habit of putting the hand before the mouth when coughing.

Respiratory Diseases.—Respiratory diseases caused more sickness and mortality than in the preceding year :—

Period.	Respiratory Diseases.		Pneumonia.	
	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.
1886–95	30	·17	3	·60
1897	26	·70	3	·60
1898	29	·77	3	·61

Of the commands, the Punjab had, as usual, the highest death-rate. As to groups, the greatest prevalence was, as usual, in the Indus Valley. Only for a few stations of the most affected groups, VI., VII., and XII*b*., are explanations given in the reports. At Sialkot and Ferozepore the cases were mostly catarrhal ; at Mooltan, cold in the early morning and at night was blamed, while the medical officer of Rawalpindi says :—

The large number were, as usual, simple catarrhs ; 7* only were cases of pneumonia. This satisfactory return is considered to be due to réveillé being sounded at 7 a.m. instead of 6, which had been the hour in the earlier part of the winter of 1895–96. The decrease in the number of cases of ague in the weekly returns of January, 1896, after the change was made was very noticeable. It will be remembered that the altitude of Rawalpindi is over 1,700 feet, and that very cold winds prevail. The alteration of the hour of réveillé had unquestionably a wholesome effect on the health of the troops.

The admission-rate from pneumonia, though slightly lowered, was practically unchanged, while mortality rose a little. Of the commands, the Punjab had the highest death-rate, as usual. The Indus Valley was, as usual, the group in which pneumonia was most prevalent, the Hills and Upper Sub-Himalaya coming next. Nowshera and Peshawar had the highest ratios in the Indus Valley. At Peshawar the pneumonia is said to have been of a low type, attacking men reduced by malaria ; and in four of the cases both lungs were affected. The Tirah Field Force lost only three men in 1898 from pneumonia.

The number of European soldiers constantly sick from pneumonia was nearly 14, against 18 in 1897, and the average duration of a case, 27 days, against 31.

Dysentery and Diarrhœa.—The admission and death rates from dysentery and from diarrhœa fell very much, fell, in fact, to normal after the unusual elevation of the preceding year :

Period.	Dysentery.		Diarrhœa.	
	Admissions per 1,000.	Deaths per 1,000.	Admissions per 1,000.	Deaths per 1,000.
1886–95	30	·73	32	·06
1897	46	2·53	33	·23
1898	30	·78	27	·04

* Excluding a case of broncho-pneumonia.

Dysentery was most prevalent in the Bengal Command and in the Bengal-Orissa Group. The same group, but the Madras Command, had the highest percentage of dysentery in total cases, as may be seen in Tables on pp. 42 and 44. It is usual for Bengal-Orissa to have a high dysentery ratio. Dysentery was distributed with some degree of evenness throughout the months of the year, the maximum month being August and the minimum December; and Barrackpore, Dum-Dum (both in the Bengal-Orissa), Shwebo, Jubbulpore, as well as the plains depôts, had very high ratios. At Shwebo the cases were mild, at Jubbulpore the disease was "not traceable to any particular cause," at Dum-Dum it was ascribed to wet and damp. The medical officer at Barrackpore considers that even the imperfect measures hitherto carried out against the turbidity of the water and the water-logging of the soil have been productive of some good, and places his hopes for the amelioration of the disease on the completion of the drainage scheme.

Legge states that a virulent form of the *bacillus enteritidis sporogenes* (Gaertner) was the cause of an outbreak of "colitis" in the Derby County Asylum, and that a non-virulent form of the same bacillus was present in the sweepings from the wards. Others have found the *bacillus coli*, the *amoeba coli*, etc. But notwithstanding all that has been done, investigations into the causation of dysentery have not yet got beyond the grouping stage.

Hepatitis.—The admission and death rates from hepatitis, including abscess of the liver, rose from 20 and 1·32 respectively in 1897 to 21 and 1·59 in 1898.

Venereal Diseases.—From venereal disease the admission rate for India was 362·9, against 485·7 in the previous year and 511·6 in 1896. In other words, in 1898 for every 1,000 men there were nearly 123 fewer admissions to hospital for venereal disease than in 1897. From the reports of medical officers, it appears that this decrease was partly unreal, and due to the widespread adoption of the system of treating venereally-affected men as out-patients; and partly real, and due to the introduction of continuous and more prolonged treatment of the sick, to measures adopted under the new cantonment rules, to the placing of certain bazaars and cities out of bounds on account of the plague, and to the employment of a certain number of men on field service.

In 1898 there were 2,201·81 (against 2,991·59) men constantly sick in hospital from venereal disease—equivalent to over two regiments. Some medical officers specially notice the influence of the out-patient system in reducing the number constantly sick in hospital.

Excluding from the calculation (because data for them are not available) men on field service, and men of the Malakand Force and of the Khyber Force and Brigade, the average stay of a case of venereal disease in hospital was 33·31 days (against 33·32); and the total loss of service was about 803,661 days (against 1,091,930).

There were 17 deaths (0·25 per 1,000 of strength) and 569 invalidings (8·40 per mille)—against 23, or 30·4 per 1,000 of strength, and 662, or 9·68 per 1,000—*directly* attributed to venereal disease.

The ratio of venereal disease to strength increased in 17 stations and decreased in 87. The only ratio over 900 per 1,000 of strength was that of Shahjahanpur, a station which had the highest ratio in 1897 also. Next came the ratios of Fatehgarh, Pachmarhi, Dinapore, Saugor, Calicut, Benares, Amritsar, and Cawnpore.

The greatest increases of ratio (increases of more than 150 per 1,000) were at Pachmarhi in the Bengal Command, Lower Topa in the Punjab Command, Calicut in the Madras Command, and Ahmednagar in the Bombay Command. But the strength of some of these stations was low. The greatest decreases of ratio (decreases of more than 400 per 1,000) were at Sitapur and Chakrata in the Bengal Command, Solon in the Punjab Command, Shwebo in the Madras Command, and Nasirabad in the Bombay Command.

All the commands shared in the decrease. The Madras Command had the lowest ratio, and, as usual, the Bengal Command the highest.

In 39 stations (against 49) the admission rate for secondary syphilis was over 100 per 1,000 of strength; and in 47 other stations (against 21) it was over 75 per 1,000.

For India the ratio of primary syphilis *plus* soft chancre diminished by 56·7 per 1,000 of strength, the ratio of secondary syphilis by 14·8 per 1,000, and the ratio of gonorrhœa by 51·2 per 1,000. The secondary syphilis ratio had been increasing in the preceding two years.

In 1898 the Madras Command had the highest ratio for primary syphilis ; *plus* soft chancre, and, as usual, for secondary syphilis ; and the Bengal Command the highest ratio for gonorrhœa.

The following table shows the admission-rate for venereal disease as far back as the records for India as a whole permit. The heading " primary syphilis " includes the soft sore throughout :—

Year.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Disease.	Year.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Disease.
1872	61·2	22·4	179·0	1886	157·9	33·3	389·5
1873	53·4	20·4	166·7	1887	142·1	29·4	361·2
1874	68·3	25·2	192·7	1888	142·1	32·4	370·6
1875	67·1	25·1	205·1	1889	225·1	51·2	481·5
1876	59·8	23·9	189·9	1890	220·7	66·3	503·5
1877	65·2	22·1	208·5	1891	159·2	60·0	400·7
1878	95·3	22·0	271·3	1892	161·1	57·8	409·9
1879	79·2	24·5	234·8	1893	213·6	61·6	466·0
1880	87·9	23·1	249·7	1894	248·1	74·6	511·4
1881	92·0	23·1	260·5	1895	239·0	84·9	522·3
1882	87·6	23·2	265·2	1896	226·4	97·7	511·6
1883	87·2	23·5	270·3	1897	201·7	101·9	485·7
1884	90·2	24·4	293·9	1898	145·0	87·1	362·9
1885	122·1	28·7	342·7				

The decrease in the total ratio continued, and the ratio of 1898 was the lowest since 1887. The secondary syphilis ratio also fell for the first time since 1892.

Invaliding.—In the whole army of India 2,580 men were invalided, or 38·09 per 1,000 of strength, against 2,258 and 33·01 in the preceding year, the increase being greatly due to the large number of men invalided for ague. The ratio for the decennium 1886–1895 was 24·34. The proportion of invalids to strength was lowest in the Bombay Command, and highest, as before, in the Madras Command.

Twenty-eight per cent. of the total number invalided were discharged as unfit for further service. The following table shows that this percentage was low. It should be mentioned, however, that the question in the case of each soldier as to whether the disability necessitates discharge is revised in England by a medical board ; so that the Indian figures do not show the real final disposal of invalids.

—	1894.	1895.	1896.	1897.	1898.
India	39	33	39	34	28

The following table shows the diseases which accounted for not less than 1 per 1,000 of strength :—

Invaliding Ratios per 1,000 of Strength.	—
Syphilis and gonorrhœa	8·40
Malarial fevers	7·16
Debility	2·69
Dysentery	1·87
Disordered action of the heart	1·80
Tubercle of the lungs	1·56
Valvular disease of the heart	1·45

The ratio of invaliding from mental diseases decreased, and was considerably below the decennial ratio as shown in the following table. There were 24 cases of melancholia, 12 of mania, and 24 of other forms of insanity.

	Ratios per 1,000 of Strength.	—
1886–95		1·19
1897		1·39
1898		·89

Invaliding according to age and Indian service.—The percentage of men who were invalided while under 25 years of age to the whole number invalided was 62, against 63 in 1897. The percentage of men under 25 in the strength of the army was 54, against 55.

Of the total number of men invalided, 33 per cent. were of less than two years' service, and 83 per cent. were of less than five years' service. With this is to be considered the fact that 82 per cent. of all the men in the strength of the army were of less than five years' service.

With regard to individual diseases the highest invaliding ratio per 1,000 of strength from venereal disease was in the age-period 20—25, and the relative liability for that period was 39 per cent. ; the actual number invalided for venereal disease in the same age-period was 353 ; of 100 invalided in the same age-period, 23 were due to venereal diseases, a proportion not quite so great as in the next age-period ; and of the total invalided for venereal disease at all ages 32 per cent. were in that same age-period. The residence period 1—5 years, and especially 3—4, had the largest proportion of invaliding for venereal disease.

Statistics of officers.

The vital statistics of officers show that the death-rate for the British Army was 16·26, and that for the Indian Army 10·18, both much lower than in the preceding year. The number of deaths from enteric fever was greater than in 1897 among British officers only, remaining the same in the case of Indian officers. Enteric fever caused, as usual, more deaths among the British than among the Indian officers, apparently because Indian officers have to serve first with British regiments, and it is known that youthful and newly-arrived men are more liable to take the disease than others. Another reason suggested is that food and drink, table and kitchen arrangements, are not so well looked after in British messes as in Indian.

The invaliding and death-rates were higher than for men, the admission-rate lower ; and the same was the case in 1897. The admission-rates from ague, tubercle of the lungs, and venereal diseases, and the death-rates from enteric fever and hepatic abscess, were lower than among the men. The chief causes of admission among officers were ague and simple continued fever ; and among the diseases with raised admission-rates were congestion and inflammation of the liver, simple continued fever, enteric fever, and influenza, the ratios from small-pox, cholera, malarial fevers, tubercle of the lungs, bowel complaints, abscess of the liver, and venereal diseases being lessened. Enteric fever was the chief cause of death ; the ratios from dysentery, circulatory diseases, and enteric fever being raised, and those from hepatic abscess, heat-stroke, and remittent fever reduced to zero.

There were only three cases of cholera, two at Thayetymo and one at Lucknow. There were 11 cases of enteric fever among the officers of the Tirah Field Force. The greatest numbers of cases of enteric fever at individual stations were 8 at Quetta, 7 at Murree, and 7 at Lucknow. Some hints as to the etiology of enteric fever at these and other stations will be found in pages 57 to 60. At Umballa one officer was admitted from the club, where the kitchen and scullery arrangements are said to have been very bad.

Statistics of women.

On the whole, the health of the women was somewhat worse in 1898 than in 1897, the rise in the admission and death-rates more than counterbalancing the fall in constantly sick :—

Period.	Average annual strength.	Admission-rate per 1,000.	Constantly sick rate per 1,000.	Death-rate per 1,000.
1886–95	31,881	815·2	32·1	17·00
1897	3,203	768·3	38·2	15·30
1898	3,118	772·9	37·9	16·04

The chief causes of admission were debility, ague, and the diseases peculiar to women. Among the diseases which caused increased admission were enteric fever, remittent fever, simple continued fever, influenza, respiratory diseases, and diarrhœa ; while from cholera, small-pox, ague, tubercle of the lungs, dysentery, puerperal affections, and the diseases peculiar to women, admission was lessened. Debility caused over 34 per cent. of the total sickness, and ague nearly 19 per cent.

The chief causes of death were enteric fever and puerperal affections. Among the diseases which gave increased mortality were enteric fever, hepatic abscess, puerperal affections, and malarial fevers. Mortality from cholera, tubercle of the lungs, pneumonia, and dysentery was diminished. Enteric fever caused 30 per cent. of the total deaths, and puerperal diseases 14 per cent.

Statistics of children.

That the health of the children was better than in 1897 may be seen from the following table, the fall in the death-rate more than counterbalancing the rise in the admission and constantly sick rates :—

Period.	Average annual strength.	Admission-rate per 1,000	Constantly sick rate per 1,000.	Death-rate per 1,000.
1886–95	59,695	581·8	22·7	46·72
1897	5,744	572·1	26·7	50·49
1898	5,592	606·6	28·8	41·13

The chief causes of admission were ague and respiratory diseases. Among the diseases with raised admission-rates were measles, whooping cough, ague, enteric fever, respiratory diseases, simple continued fever, diarrhœa, and eye diseases ; while admission from cholera, small-pox, remittent fever, influenza, tubercular diseases, and dysentery was lessened. Ague caused over 20 per cent. of the total sickness, and respiratory diseases over 11 per cent.

The chief causes of death were diarrhœa, convulsions, respiratory diseases, debility (including immaturity at birth) and teething. Among the diseases from which there was increased mortality were diarrhœa, remittent fever, enteric fever, diphtheria and croup. Mortality from cholera, small-pox, tubercle, teething, debility, respiratory diseases, convulsions, and dysentery was diminished. Diarrhœa caused over 22 per cent. of the total deaths, convulsions over 10 per cent., and respiratory diseases nearly 10 per cent.

Native Troops.

With a fairly normal year—a dry settled hot weather and monsoon rains above rather than below the standard in most parts of the country—the health of the Native troops was also fairly normal, and better than in the preceding year. Though there was an increase of influenza and respiratory disease, there was a great reduction in cholera :— **Sickness and mortality in 1898.**

Year.	Average strength.	Ratio per 1,000.							
		Admissions into hospital.	Constantly sick.	Deaths from					Mortality, including absent deaths.
				Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All causes.	
1886–95 ...	123,302	976	34	1·32	1·34	3·02	·78	12·43	16·72
1897	129,802	839	31	·52	1·04	2·73	·67	13·12	14·90
1898	126,036	816	33	·33	1·08	3·77	·49	11·07	13·33

The chief cause of admission was ague. Among the diseases with raised admission-rates were influenza, remittent fever, respiratory diseases, and tubercle of the lungs. Among those with lessened rates were cholera, small-pox, dysentery, diarrhœa, and ague. Ague caused 41 per cent. of the total admissions.

The chief causes of death were pneumonia and remittent fever. Among the diseases which caused increased mortality were remittent fever, pneumonia, and enteric fever. Among those from which mortality was lessened were cholera, small-pox, ague, tubercle of the lungs, and debility. Pneumonia caused 34 per cent. of the total deaths, and remittent fever 10 per cent.

The total number invalided for discharge was 1,772, and the chief causes of invaliding were debility, malarial fevers, respiratory diseases, and venereal diseases.

If the following table be compared with that on page 24 it will be seen that the Native soldier suffered less from enteric fever, ague, remittent fever, simple continued fever, diarrhœa, hepatitis, and venereal disease ; equally from influenza and cholera ; and more from tubercle of the lungs, respiratory diseases, especially pneumonia, dysentery, and small-pox, than his European comrade. He also suffered more from scurvy. These relations are usual, except in regard to cholera, influenza, ague, remittent fever, and tubercle of the lungs.

Ratios of Commands.

—	Ratio per 1,000 of the Average Strength.					
	Bengal Command.	Punjab Command.	Madras Command.	Bombay Command.	Hyderabad Contingent.	Army of India.*
I.—Average Annual Strength	25,036	42,515	22,575	24,520	6,304	126,036

* Including those Imperial Service Troops that went on Field Service.

Of the commands, the Punjab was the most unhealthy, and it was more unhealthy than in the previous year. Its death ratios from cholera, malarial fevers, and pneumonia were raised, while those from small-pox, enteric fever, tubercle of the lungs, and debility were lowered. The Punjab had the highest admission, the highest constantly sick, and the highest death-rate ; and the Hyderabad Contingent the lowest. The highest ratios of mortality from ague, tubercle of the lungs, and diarrhœa were in Bengal ; the highest from enteric fever, remittent fever, pneumonia, other respiratory diseases, and dysentery in the Punjab ; and the highest from cholera in Madras.

Burma.—The following table shows the statistics of all the native troops serving in Burma and the Andamans. Of these troops, in 1898 about 99 per cent. belonged to the Madras Army :—

Years.	Average annual strength present.	Ratio per 1,000.						
		Admissions into hospital.	Constantly sick.	Deaths from				
				Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All causes.
1891	11,401	1,676	76	1·75	2·98	1·84	4·03	36·31
1892	11,333	1,349	57	2·29	2·29	2·29	3·09	29·12
1893	10,326	1,092	48	·87	1·45	2·42	1·36	19·85
1894	10,500	809	35	1·43	·95	1·14	1·43	13·90
1895	9,952	827	37	·80	·50	·80	·80	10·55
1896	9,605	830	38	—	·94	·73	1·35	9·58
1897	8,661	802	35	·46	·46	·92	·23	6·58
1898	7,195	800	31	·14	1·11	·42	·28	8·06

The table shows that the death-rate, which had been reduced year by year, went up somewhat in 1898, though sickness was less than in the preceding year. A comparison of the health of the troops in the Burma Coast group of stations with that of the troops in the Burma Inland group may be made by the use of the table on the opposite page.

* Including Group Extra-India.

Trans-Frontier stations.—The following statistics are those of the regiments stationed beyond the North-Western Frontier and in Baluchistan. The garrisons of Gilgit, Chitral, and the Malakand are not included :—

Year.	Average annual strength present.	Ratio per 1,000.						
		Admissions into hospital.	Constantly sick.	Deaths from				
				Cholera.	Remittent fever.	Pneumonia.	Dysentery.	All causes.
1898	9,468	1,492	44	—	1·06	8·56	·63	15·31

If this table be compared with that for India on page 69, it will be seen that the general ratios of the trans-frontier troops were considerably less favourable than those of India as a whole, a high death-rate from pneumonia being also a salient feature.

Geographical Groups.—The table which follows shows that for the decennium the highest constantly sick ratios were those of Groups II, III, I, IV, and XII, while the highest in 1898 were those of XII, III, and IV. Both for the decennium and in 1898 the mortality from respiratory diseases was greatest in the Indus Valley. Cholera mortality was below the decennial figure in all the groups except Assam and Southern India, and was highest in Assam :—

		Ratio per 1,000 of Strength.

	Respiratory diseases	·45	1·49	1·68	·98	3·18	2·99	7·86	2·46	1·72	1·07	1·82	3·09	3·23
1898.	Constantly sick rate...	25·9	35·7	40·3	39·9	33·5	32·4	39·0	26·3	27·1	36·3	33·4	44·5	32·9
	Death-rates from—													
	Cholera	—	—	8·40	·34	·18	·22	—	—	—	—	1·77	·11	·33
	Respiratory diseases	·72	·92	3·23	1·37	1·78	5·06	9·62	2·83	2·01	1·44	2·15	5·65	4·13

In the table on page 71 it may be seen that Burma Coast had the lowest ratios from ague and pneumonia ; Burma Inland the highest from ague, and the lowest from simple continued fever ; Assam the highest from cholera, enteric fever, tubercle of the lungs, dysentery, diarrhœa, and venereal desease ; Bengal-Orissa the highest from influenza ; Indus Valley the highest from remittent fever, pneumonia, other respiratory diseases, and, along with the Hills, from scurvy, and the lowest from venereal desease ; Deccan the lowest from tubercle of the lungs, and from respiratory diseases other than pneumonia ;

Western Coast the highest from simple continued fever and from hepatic congestion; Southern India the highest from small-pox, and the lowest from dysentery and diarrhœa; the Hills, along with Indus Valley, the highest from scurvy. The comparative prevalence of enteric fever and venereal disease in Assam is due to the number of Gurkha troops there.

Stations.—Of the large stations throughout India with a strength of not less than 1,000, the following returned the highest death-rates:—Edwardesabad 40·61, Datta Khel 40·32, Dharmsala 24·33, and Meerut 23·87. The principal cause of death at Edwardesabad, Datta Khel, and Meerut was pneumonia, and at Dharmsala pneumonia and tubercle of the lungs. The garrison of Dharmsala is wholly Gurkha. Edwardesabad and Dharmsala were in the same black list in last report.

In answer to official inquiries regarding the recent outbreak of malaria at Aden, Major Anderson, I.M.S., an officer of long local experience, states his opinion that the sole cause was the heavy rainfall of 1889–90, the fever extending to places 50, 60, and even 100 miles in the interior, and that it will die out provided there is no more heavy rain. He regards chills as the exciting cause of the dysentery, though malaria and scurvy may be predisposing causes; and the climate as an important factor in the causation of the scurvy.

Principal Diseases: Influenza.—Attention having been directed to the health statistics of India, of the commands, of the geographical groups, of stations, and of regiments, it will be convenient now to consider some of the chief diseases. Influenza increased considerably, there having been 1,047 cases, 8·3 per 1,000 of strength, against 695 cases, 5·4 per 1,000 of strength, in the preceding year. This rise continues the alternation of fall and rise year by year which has obtained ever since the first outbreak of the disease in 1890. The geographical groups affected both in 1897 and in 1898 were II, IV, V, VI, VII, VIII, IX, XI, XII; I was newly affected in 1898, X was attacked in 1897, but not in 1898; while III escaped in both years. In proportion to strength the Bengal-Orissa group was most severely affected; and next to it Burma Coast, which had had no cases since 1892; but the greatest number of cases occurred in the Hills. The following table shows the monthly progress of the disease since its beginning in 1890. The maximum month varied from year to year, but over the period as a whole most cases occurred in April and March, and fewest in October and September:—

Years.	Number of Admissions into Hospital in each month.												Total.	Admitted per 1,000 of Strength.	Died per 1,000 of Strength.
	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.			
1890 ...	1	8	2,460	5,118	492	82	55	—	—	—	1	—	8,217	64·3	·41
1891 ...	—	—	1	—	105	259	123	106	51	22	17	215	899	7·0	·09
1892 ...	681	371	511	149	40	5	5	7	—	1	7	18	1,795	14·1	·15
1893 ...	8	28	65	99	95	13	9	7	—	3	53	404	784	6·2	·20
1894 ...	159	203	232	384	143	11	5	—	1	1	5	11	1,155	9·0	·16
1895 ...	26	28	53	76	110	25	60	57	19	17	31	408	910	7·0	·08
1896 ...	372	196	397	35	22	11	33	57	53	39	82	72	1,369	10·7	·30

1898 ...	110	290	280	96	180	24	1	—	1	10	32	23	1,047	8·3	·03
Total	1,454	1,185	4,099	6,074	1,271	509	313	234	167	160	251	1,154	16,871	14·6	·16

Thirty-four stations were affected against 20; 27 being newly affected, 7 affected in both years, 13 affected in 1897 but not in 1898. The greatest number of cases occurred at Bangalore, Alipore, and Dharmsala. At Bangalore the disease was confined to February and March, at Alipore to January-March, and at Dharmsala to March-May. The following table shows that in 1898 the native troops, with exactly the same

admission-rate as the European troops, were, as usual, much less severely affected than the prisoners:—

Years.	Per 1,000 of Average Strength.											
	Influenza.						Pneumonia.					
	European Troops.		Native Troops.		Prisoners.		European Troops.		Native Troops.		Prisoners.	
	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.
1890	33·4	·03	64·3	·41	78·6	·67	4·6	·90	16·7	3·96	18·5	5·71
1891	5·5	·04	7·0	·09	19·0	·29	2·6	·54	11·6	2·53	17·0	4·87
1892	12·7	·01	14·1	·15	56·7	1·26	3·5	·62	13·6	3·26	18·4	5·56
1893	·3	—	6·2	·20	6·4	·09	3·4	·70	12·3	2·75	15·9	3·95
1894	3·4	·01	9·0	·16	41·0	·43	3·7	·75	12·9	2·87	15·4	4·31
1895	7·8	·03	7·0	·08	20·3	·15	4·4	·51	17·5	4·20	16·4	4·00
1896	11·5	·11	10·7	·30	37·6	·60	5·2	·64	15·3	3·14	19·1	4·34
1897	4·0	·01	5·4	·04	8·4	·21	3·4	·60	13·0	2·73	15·6	4·24
1898	8·3	·01	8·3	·03	21·0	·33	3·3	·61	16·5	3·77	15·8	3·94

It also shows the relation of the pneumonia death-rate year by year to the admission rate from influenza, though, of course, the presence or absence of influenza is not the only circumstance which influences the pneumonia death-rate. The cases were mostly of a mild type, only four deaths being returned as directly due to influenza.

Cholera.—In the Native Army of India there were 48 cases with 42 deaths, against 112 cases with 68 deaths in the preceding year. The admission-rate was 0·3 against 0·8, and the death-rate 0·33 against 0·52. The only months quite free from the disease were August, September, and November; while the maximum was in June. The greatest numbers of cases occurred in Southern India and Assam, at Trichinopoly and Manipur. The regiment attacked at Manipur was the 44th Gurkha Rifles, and that chiefly affected at Trichinopoly was the 27th Madras Infantry. At the time the outbreak among the troops took place at Manipur cholera was raging in the valley, hardly a village round escaping. A committee, of which the president was the Principal Medical Officer, has insisted that the chief and most urgent want of Manipur is a pure, abundant, well-delivered, and properly protected water-supply. At Trichinopoly, too, the disease was prevailing in the neighbourhood when the troops were attacked, and the medical officer of the 27th states that it prevails every year from January to April.

Small-pox.—There were 26 cases of small-pox with 1 death, against 53 cases with 6 deaths in the preceding year. The admission ratio was 0·2 per 1,000 against 0·4, and the death-rate 0·01 against 0·05. In the Southern India group the cases bore the highest proportion to strength, but the maximum of cases (5) occurred in Indus Valley and Southern India. No station or regiment had more than 2 cases. The medical officer of the 7th Bengal Infantry states that the mild disease was quickly stamped out by the measures adopted, among them being special attention to vaccination, particularly among the followers.

Ague, Remittent Fever, Simple Continued Fever.—To ague was due over 41 per cent. of the sickness of the Native Army. Owing, no doubt, to the return of the seasons to the normal, the admission-rate from ague fell. The reduction was from 347 in 1897 to 335 in 1898. In 1898 Burma Inland was the most malarious group, and Burma Coast, as in the two preceding years, the least malarious; and the most malarious months were October and November, and the least malarious April and February.

Remittent fever caused nearly 10 per cent. of the total deaths, and prevailed most in August and least in December. The admission rate rose from 15·9 to 20·0, and the death-rate from 1·04 to 1·08. The medical officer of the 32nd Pioneers at Meean Meer, the regiment that had most cases, states that the disease was of a mild type. The proportion of cases returned as simple continued fever is much lower in the Native Army than in the European ; but it is pretty certain that many cases which in the latter would be so returned are in the former called ague. The simple continued fever of the Native Army was at its maximum in June, July, and May, and at its minimum in February, October, January. This was a good deal nearer the distribution of 1896 than that of 1897 had been, the seasons in 1898 having made a return to the normal. No remarks of importance are made by the medical officers. Some medical officers mention the prophylactic issue of quinine and other antiperiodics, and there is no doubt that this is a practice which ought to be strongly encouraged throughout the Native Army. There are three sets of opinions as to the results : that reduction of ague was effected, that no benefit was observed, that, while the number of cases was not reduced, the type of the disease was mildened.

Enteric Fever.—The ratio of admission from enteric fever in the Native Army in 1898 was 0·3 per 1,000 of strength, and the death-rate 0·13, against 0·4 and 0·12 in the previous year. The corresponding decennial ratios of 1886—95 are 0·2 and 0·08. The following table shows that the ratios for European troops are very unlike those for Native troops and prisoners :—

——	1886–95.		1898.	
	Admissions.	Deaths.	Admissions.	Deaths.
European troops	19·6	5·28	36·9	10·17
Native troops	·2	·08	·3	·13
Jail population	·3	·12	·2	·08

The next table indicates the fact that the total fever mortality in the two armies is not the same in amount, which proves that the difference is not altogether a mere matter of diagnosis :—

Causes of Death.	Died per 1,000 of Average Strength.		Relative Liability in Percentages.			Percentage in Deaths from all causes.	
	European Troops.	Native Troops.	European Troops.	Native Troops.	Total = 100	European Troops.	Native Troops.
Ague	·30	·58	34	66	100	1·5	5·2
Remittent fever	·37	1·08	26	74	100	1·8	9·7
Simple continued fever	·06	·03	67	33	100	·3	·3
Enteric fever	10·17	·13	99	1	100	50·7	1·2
Total	10·90	1·82	86	14	100	54·3	16·4

The total fever mortality among the Native troops in 1898 was to the total fever mortality among European troops as 1 : 6·0. For the period 1886—95, the corresponding ratio was 1 : 2·6, and for 1896 it was 1 : 4·2. Again, among the European troops 54 per cent. of all deaths in 1898 were from fevers ; only 16 per cent. among Native troops. See also Section IV, paragraph 104. As the death-rate of European troops from enteric fever in 1898 was nearly six times as great as that of Native troops from all kinds of fever, it appears, whatever may be the nature of the remittent and continued fevers from which Native soldiers died, that Native soldiers and prisoners were less liable to enteric fever than European soldiers.

The question of the immunity, or apparent immunity, of natives of India as regards enteric fever has been frequently discussed in former reports. For the opinion that natives of India are apparently exempt from enteric fever only because they have already passed through the disease in infancy, has not yet been adduced by the evidence of observed facts. But the medical officer of health of Hong Kong, after stating his belief that the alleged immunity of the Chinese is "probably due to an attack during infancy," goes on to say that the result of a careful search among the Chinese infants brought to the mortuary shows "that several such bodies have been found to present typical typhoid ulcers of the intestine." While the medical officer of Wachow returns a case in a Chinese in February and another in July, he of Chung King is still of opinion that enteric fever, pure and simple, does not occur there, though he records a case of "typhomalarial fever" in a European. Law describes two cases which may have been enteric fever in British Guiana among natives of the East Indies; but states that the disease is rare in the colony, and had never been met with in his own district. And Browne lays it down that the disease does not exist in British Honduras. On the other hand, in the Japanese Navy in 1896, there were 161 cases A *Lancet* leader adopts the view that the immunity of the Indian is real, and suggests that, for service in India, the darker complexioned Englishman of medium stature would probably be nearer the native of India in immunity than the big fair Englishman :—

> As compared with Europeans and the inhabitants of cold and temperate climates, the eastern and southern races, the Asiatic, African and mixed races, exhibit a relative immunity from . . . enteric fever, which plays such an important rôle in the medical history of all campaigns and expeditions in hot climates. Our experience in Egypt and elsewhere and that of the French in Algiers, Tunis, and other countries, have been to a similar effect. In the French expeditions, the Zouaves and troops with an admixture of Arab blood, and, in a less degree, the troops coming from Southern France, suffered less from this and other forms of fever than did those from the north. . . . Other things being equal, the nearer in physical type, temperament, and complexion the intending emigrants approach to the natives of warm latitudes in these respects the more likely are they to stand the climate and to prove healthier than fair-skinned men of larger stature. . . . For service in hot climates grown men of medium stature, spare frames, dark hair and complexion, and thick skins, may be expected to retain their health and to make the more efficient and enduring soldiers.

In the whole Native Army of India, 40 cases with 17 deaths were returned as enteric fever, as against 51 cases with 15 deaths in 1897. In not a single case does a *post-mortem* seem to have been obtained. Cases occurred in every month except November and December. The greatest number of cases was 10 at Kila Drosh, and no other station had more than three. In one of the Manipur cases the disease supervened on dysentery. At Kila Drosh exposure to the sun and fatigue are mentioned as factors in the causation; while various defects in water, milk, conservancy, etc., are pointed out, and it is stated that the Garhwalis were apparently, if not really, less liable to the disease than the Gurkhas proper. At Allahabad also exposure to the sun is mentioned; at Manipur, drinking of the prohibited water of the River Imphal; at Bakloh, impure water or milk; at Vizianagram, suspicious well water; at Madras, the drinking of impure water when at Pallavaram at musketry instruction. Two medical officers fear that, owing to the difficulty of diagnosis, they did not return all the cases of enteric fever that occurred in their regiments, having classed them as remittent fever, etc.

Plague.—In 1898 there were 94 cases of plague with 58 deaths, against 131 with 82 in 1897.

Respiratory Diseases.—Both morbidity and mortality from respiratory diseases were greater than in 1897; but allowance must be made for the fact that the ratios of 1897 were unusually low. Some of the increase at least was probably connected with the recrudescence of influenza :—

Period.	Ratio per 1,000 of Strength.			
	Respiratory Diseases.		Pneumonia.	
	Admissions.	Deaths.	Admissions.	Deaths.
1886–95...	50	3·75	13	3·02
1897	38	3·23	13	2·73
1898	45	4·13	16	3·77

Respiratory diseases are the chief cause of death in the Native Army, and in 1898 over 37 per cent. of all deaths were due to them. For respiratory diseases other than pneumonia the highest admission ratios were those of the Indus Valley and the Hills, and the lowest, as in the preceding year, that of the Deccan. Of commands, the Punjab had, as usual, the highest death-rate, and Bengal the lowest, except the Hyderabad Contingent. Non-pneumonic respiratory diseases were most frequent in the 16th Bombay Infantry while at Fort Sandeman, and in the 2nd Sikh Infantry and the 3rd Punjab Cavalry while at Kohat. Cold weather, cold winds, and chills are assigned as the exciting cause.

Pneumonia.—The admission and death rates from pneumonia, as may be seen from the table given in the preceding paragraph, rose considerably, and were above the decennial ratios. In the table on page 74 is displayed the relation from year to year between pneumonia and influenza. The admission ratio was highest, as usual, in the Indus Valley; and the death-rate was also highest there. Both in the Indus Valley and in the Hills, but especially in the former, pneumonia was most prevalent in the cold months; and the same was the case for India as a whole.

Dysentery, Diarrhœa.—From dysentery the admission-rate was much, and the death-rate considerably, lower than in the preceding year. The highest admission ratios were, as in the previous year, in the Punjab Command and the Assam group, and the highest death-rates in the same. The death-rate of Native troops from dysentery was to that of European troops as 1 : 1·6; and the percentage of dysentery in total deaths was 4·4 in the case of Native troops, and 3·9 in the case of European troops. Again, the case-mortality of Native troops was 1·05 per cent., while that of European troops was 2·29. The admission rate of Native troops was, however, as usual much higher than that of European troops, 44·0 to 29·8.

Venereal Diseases.—The following table is given to compare with the corresponding one for European troops on page 66.

Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Diseases.	Years.	Primary Syphilis.	Secondary Syphilis.	Total Venereal Diseases.
1877	11·5	5·3	26·7	1888	13·5	5·4	31·5
1878	16·3	5·8	37·5	1889	16·6	6·4	38·9
1879	16·5	7·0	37·1	1890	16·0	6·9	41·1
1880	15·0	5·8	33·3	1891	13·6	6·9	37·9
1881	17·9	7·2	39·5	1892	14·1	7·9	39·6
1882	14·7	5·9	34·4	1893	13·3	9·0	36·4
1883	13·0	6·5	31·6	1894	13·8	8·2	32·3
1884	11·0	5·3	27·9	1895	13·1	7·3	31·3
1885	11·2	5·9	30·1	1896	15·5	8·9	37·2
1886	13·7	6·0	28·1	1897	16·1	9·0	40·8
1887	12·6	6·1	27·4	1898	14·3	11·5	40·0

The figures for India are not available for the years before 1877. Primary syphilis includes the local sore throughout. All the venereal ratios of Native troops run at a much lower level than those of European troops; and they have remained comparatively steady during the years of which the statistics are given.

A comparison of tables on pages 42 and 69 will show that, leaving the Hyderabad Contingent out of account, the lowest ratios for both European and Native troops were, as in 1897, those of the Punjab Command. For European troops the Madras Command

had the highest ratio, and for the Native troops, the Bengal Command. In all the commands the ratios of Native troops were much lower than those of European troops.

Whilst among the European troops an average strength of 67,741 gave 24,585 admissions, in the case of the Native troops an average strength of 126,036 gave only 5,040 admissions. In other words, there were only 40 admissions for every 1,000 men among Native troops, against 363 for every 1,000 among European troops.

The admission-rate was 0·8 per 1,000 less than in 1897. There were 8 deaths and 99 invalidings *directly* due to venereal disease. In 36 stations out of 198 the admission rate from secondary syphilis was over 20 per 1,000 of strength, and in 44 other stations it was over 10 per 1,000 of strength.

For India the ratio of primary syphilis *plus* soft chancre fell by 1·8 per 1,000 of strength; that of secondary syphilis rose by 2·5, and that of gonorrhœa fell 1·5, the net result being a fall of 0·8 for all forms of venereal taken together, as noticed above.

Jails.

The health of the prisoners of India was much better in 1898 than in 1897. There was little cholera, though more influenza, and the usual chief heads of mortality, except phthisis pulmonalis, showed a reduction. The year 1898 was quiet, settled, and dry; the hot weather was hotter and drier than usual; the monsoon commenced slightly late, but quickly extended over the country, and gave rain in excess of the normal, or only slightly below it, to the greater part of India, the only regions of decided deficiency being parts of the Punjab, Rajputana, and Berar:—

Year.	Average strength.	Ratio per 1,000.									
		Admissions into Hospital.	Constantly Sick.	Deaths from							
				Cholera.	Remittent Fever.	Dysentery.	Diarrhœa.	Respiratory Diseases.	Phthisis Pulmonalis.	Anæmia and Debility.	All causes.
1886–95 *	960,973	1,097	39	2·74	1·49	6·80	2·82	5·85	2·50	2·52	32·20

* Excluding subsidiary jails.

The chief causes of admission to hospital were ague, dysentery, abscess, and diarrhœa. Among the diseases with raised admission-rates were influenza, pneumonia, tubercle of the lungs, other respiratory diseases, and spleen diseases; while the rates from cholera, small-pox, debility, fevers, scurvy, and bowel complaints were lowered. Ague caused 35 per cent. of the total sickness, and bowel complaints 15 per cent.

The chief causes of death were dysentery, pneumonia, tubercle of the lungs, debility, and diarrhœa. Among the diseases with increased mortality was tubercle of the lungs. Among those with lessened mortality were cholera, small-pox, dysentery, diarrhœa, fevers, respiratory diseases, and debility. Dysentery caused 22 per cent. of the total deaths, pneumonia 15 per cent., and tubercle of the lungs 13 per cent.

Proportion of prisoners in population.—The following statement shows for each administration, except the Andamans, the proportion of prisoners in 10,000 of the population. Some of the prisoners of each province have been transported to the

Andamans, and these are necessarily excluded from the calculations, so that the ratios are all somewhat too low :—

Administrations.	Period.	General Population according to Census of 1891.	Prisoners.		
			Average Number.*	Proportion per 10,000 of Population.	Deaths per 1,000 of Average Strength.*
Burma	1897	7,605,560	13,435	17·7	24·12
	1898		12,674	16·7	20·59

* Excluding subsidiary jails.

The prisoners of the Punjab alone were more unhealthy than in the previous year. In 1898 the three most unhealthy administrations were, in order, Assam, the Central Provinces, and the Andamans, and the three most healthy were, in order, Berar, Burma, and Bombay.

As compared with the decennial ratios, cholera mortality was everywhere, except in the always cholera-free Andamans, greatly reduced; the amount of reduction being greatest in Burma, Madras, and the Central Provinces; dysentery mortality was somewhat increased in five administrations, and greatly reduced in five, the reduction being greatest in Assam and Bengal, administrations in which high ratios are usual; diarrhœa mortality was reduced in all administrations, but especially in Madras and Assam. Mortality from respiratory diseases was diminished in all provinces except Madras and Bengal, the diminution being greatest in the Punjab and Bombay; phthisis mortality rose in all the provinces except Assam and Bengal, the rise being greatest in Madras, the Central Provinces, and the North-Western Provinces and Oudh.

It will be noticed in the above table that the provinces with total death ratios most below their decennial ratio were Burma, Assam, and Bengal; and that those with ratios most below the ratio of the previous year were the Central Provinces (less by 100·35, or 74 per cent.), Madras and Berar. Only the North-Western Provinces and Oudh had a death ratio higher than that of the decennium, and only the Punjab a death ratio higher than that of 1897.

The Andamans had the highest death-rate from tubercle of the lungs, and the lowest from pneumonia; Burma the lowest from respiratory diseases other than pneumonia; Assam the highest from cholera, ague, remittent fever, respiratory diseases other than pneumonia, diarrhœa, and debility, but no mortality from tubercle of the lungs; the Punjab the highest from pneumonia; Berar the lowest from dysentery; the Central Provinces the highest from dysentery; and Madras the lowest from debility.

In each hundred of the total deaths the proportion of tubercle of the lungs and of dysentery was greatest in the Andamans; of cholera and diarrhœa in Assam; of pneumonia in the Punjab; of remittent fever in Bombay.

The death-rates, or the known circumstances of the general population, and of the jail population, may sometimes be found to throw light one upon the other. If, for instance, the death-rate in a jail from dysentery and diarrhœa is strikingly higher than the rate recorded among the people in the surrounding district, the presence of a preventable cause at work inside the jail is suggested. Again, the presence of influenza in some of the jails actually gave a clue to the explanation of an extraordinary high death-rate from "fevers" in a certain province in the early part of a recent year.

The strongly held opinion of Lieutenant-Colonel Bate, Inspector-General of Prisons, Punjab, that the sickness and mortality occurring among the jail population in his province is to a great extent preventable, but that satisfactory results can only be obtained by unremitting attention to their duties on the part of those responsible for the welfare of the prisoners from day to day, is of general application. Careful attention to detail is essential to success in jail hygiene, as it is in most other matters; but it is vain to hope that the labours of medical superintendents, however capable and devoted, will entirely make up for the evil effects of bad sites and unsuitable buildings; and time and trouble have too often to be given to the treatment of patients, who, but for the condition of their surroundings, would never have been sick. The greatest care has been given to water-supplies for very many years, and the importance of good cooking has been recognized; but pure air is as necessary as pure water, and until it is possible to ventilate thoroughly the sleeping barracks in the cold nights of winter without chilling the occupants, there is no hope of banishing pneumonia from the jails, or of bringing respiratory diseases and tubercular affections within the limits to which they ought to be reduced. It is sometimes said that convicts are pampered, and in some few cases this may be true; but as long as jail death-rates remain as high as they now are, a general charge of this nature would be difficult to justify.

Andamans.—The Senior Medical Officer reports that all necessary arrangements have been made to meet the results of a possible importation of plague. It was found that hard labour in the cellular jail caused an alarming loss of weight in the convicts. He continues:—

> The vegetable supply is a weak point; it is extremely difficult to grow antiscorbutic plants in these islands, especially during the rains, and no indigenous plant of this description exists to my knowledge. The want of antiscorbutic properties in the vegetables is made up by an issue of tamarind, which is cooked in the food. Previously the tamarind was issued in a separate form; but the convicts, especially those from Northern India, disliked the acid taste, and did not eat it. Now they have no option in the matter. The result is satisfactory. Great efforts are being made to grow large quantities of limes, tamarinds, and such antiscorbutics as will grow freely in the settlement. .....The difficulties and defects in the water-supply have frequently been noticed, and have received a good deal of attention. Still, the water-supply is not satisfactory. The general system of supply is from rain and surface water collected in open tanks. The catchment area is protected, but rain water is not a satisfactory source of supply. .....No waters from the open tanks have ever given a good analysis, but they are potable. The defects are counterbalanced by the use of Larymore's patent boilers, and the use in certain cases of permanganate of potash. Still, the settlement may boil the water, but it is quite a different business to make the convicts drink it, especially in the rains. The water supplied to the 350 or 400 men employed intramurally suits the men, and no disease can be traced to it; in fact, these men are the healthiest in the islands.

Burma.—The average number of prisoners, which has been steadily decreasing since 1896, when the maximum was reached, fell to 12,674; but in spite of the decrease in the number of the prisoners in 1898 to a figure far below that for which accommodation is provided, there was chronic overcrowding in the jails at Insein and Henzada, and occasional overcrowding elsewhere. In spite of the reduction of its population, and the care bestowed on the "water-supply, feeding, clothing, and housing" of the inmates, the prison at Moulmein retains its reputation for unhealthiness. The very high admission-rates for bowel complaints in this jail are noteworthy. Owing to its unhealthiness it was finally reduced from the status of a central prison to that of a district jail in the first quarter of 1898. The Inspector-General of Prisons makes, from his long experience, some strongly favourable remarks as to the employment of jail gardens for the systematic disposal of the night-soil. Three of the jails, supplied with drinking water containing an unusual amount of solid matter and of chlorine per gallon, show no ill effects therefrom in the persons of their prisoners.

Assam.—The improvement in the health of the prisoners is attributed by the Inspector-General to the influence of the improved dietary; to the careful selection of prisoners for extramural labour; to the prophylactic administration of quinine and iron in the unhealthy season; to continued attention to the dieting and treatment of the weakly; and to the almost complete absence of cholera, from which there was only one death during the year. The Sanitary Commissioner of Assam points out, however, that 1898 was an unusually healthy year, and that the convicts shared in the general good health. That this is, in a measure, true is shown by the fact that the death-rate among convicts who had been for less than six months in jail, the number of whom averages more than all the rest of the convicts put together, was much the lowest. But a comparison of the mortuary statistics of the province as a whole with those of the jails during the last few years seems to indicate that much of the amelioration of 1898 was due to improved

hygiene. The Inspector-General convinced himself that the increase in the death-rate of Tezpur Jail was not due to the conditions of jail life or to want of care on the part of the officials, and that everything that could be done for the health of the prisoners had been done. Five of the deaths in that jail appear to have been due to *kala azar*.

Bengal.—The most noteworthy features of the year were the large decrease in the number of prisoners admitted, accompanied, however, by only a moderate decline in the daily average number of convicts; a remarkable immunity from severe outbreaks of cholera or other epidemic diseases; a very moderate sick-rate; and the lowest death-rate recorded. The year was no doubt an exceptionally healthy one; but a study of the figures of recent years shows how much has been achieved by the earnest attention of the jail administration, and by the honest work of the executive officers. The jails of the province afford ample accommodation for the number confined, although the special provision for females under trial seems to be inadequate. Owing to the difficulty or impossibility of distributing short-term convicts and under-trial prisoners, the average numbers of the former were in excess of the accommodation provided in 14 jails, and of the latter in 19 jails, and it was unfortunately found necessary occasionally to utilize worksheds as dormitories. The Inspector-General of Prisons says:—

> In all the jails which I have visited I found the superintendents keenly alive to the importance of all the arrangements in connexion with the water-supply. . . . . The extensive works at Buxar for pumping water from the Ganges, and for filtering, boiling and distributing it, were nearly completed at the close of the year. Alipore [Larymore] boilers were supplied to Monghyr, Bhagalpur, and Purneah Jails. New Pasteur filters were put up in the Dinajpur and Jalpaiguri Jails; those at Dumka and Motihari are reported to work satisfactorily; while that at Bogra got out of order in October. All wells from which drinking water is drawn are cleared of silt during the hot weather, and are frequently disinfected with permanganate of potassium. Samples of the drinking water used in all jails were sent for analysis to the Chemical Examiner to Government.

North-Western Provinces and Oudh.—Owing chiefly to the improvement of the material condition of the people in these provinces, there was a considerable reduction in jail population. Not only were the numbers much less than in the preceding year, but the health of the newly-admitted prisoners was much better; and, as the year was an exceptionally healthy one, the only important general factors militating against the health of the prisons as a whole in 1898 were the legacy of weakly prisoners convicted in the preceding year, and the overcrowding that took place in nearly three-fifths of the jails, including the six central ones. Every effort was made to avoid undue crowding by transfers, but the difficulties were increased by the large number of long-term prisoners.

Punjab.—There was a marked deterioration in the health of the jail population of the Punjab, with a considerable increase in the prevalence of dysentery of a severe type. The Inspector-General considers that, speaking generally, this is ascribable to the serious deterioration of health caused among prisoners by the prevalence of malarial fevers during the autumn of 1897; and thinks it also possible that the robustness of the prisoners received in 1897 and 1898 had been more or less impaired prior to admission to jail by the scarcity that prevailed in the province during the former year. The vital statistics of the provincial general population fully confirm this theory. There was a relationship between the death-rates of the civil population and of the convicts, but the relationship was in kind rather than in degree. The same diseases and the same seasonal influences acted effectively on both, but not in the same proportion; and there seems to have been some unfavourable condition of jail life at work. Cases of pneumonia were far more numerous than in 1897, and the increase in the Delhi Jail suggests special inquiry into the cause.

Bombay.—Difficulties caused by the presence of plague hampered transfers, and inevitable overcrowding occurred throughout the year in 10 out of the 15 jails. Some relief was afforded by the transfer early in May of 231 convicts to Sind, and, later in the same month, of 210 male life-convicts to Port Blair. Pneumonia in a bad form prevailed in the Sind gang in January; and the Shikarpur Jail, which, it is hoped, will soon disappear, and be replaced by a new prison at Sukkur, maintained its evil reputation for fatal pneumonia. On the other hand, in the Hyderabad Central Prison no prisoners died from diarrhœa, pneumonia, or other respiratory diseases, and only one, and that a man under trial, from dysentery. For the first time for 12 years there was no cholera in any of the Bombay jails, sub-jails, or lock-ups.

Berar.—With the return of prosperity there was a large decrease in the amount of crime, and the number of persons imprisoned was less than half the number imprisoned in 1897, and considerably lower than in any recent year. The reduction in the number of admissions to prison was not, however, sufficient to balance the great excess in the

population with which the year opened, so that the average strength in confinement throughout the year was greater than that for which accommodation is provided. The year was a peculiarly healthy one in Berar, and the convicts shared in the general good health. There was no plague, and little cholera; and scurvy also was almost absent from the jails.

Central Provinces.—Several jails were overcrowded at the beginning of 1898, but, as comparatively few persons were admitted to prison during the year, the gradual release of the famine convicts soon brought the numbers in confinement to normal, and before the end of the year accommodation in every prison was more than sufficient. The famine crisis of 1897, and the consequent admission of large numbers of starved and diseased prisoners, resulted in an abnormal rise in the sickness and mortality in that year. With the return of prosperous seasons and cheap prices, the distress and hardship of the previous year abated, but the ill effects of the famine continued to be visible in the new admissions to jail during the early months of 1898, and the sick-rate was high. The comparatively low death-rate with the high average sick-rate indicates either that the diseases from which the convicts suffered were much more amenable to treatment than formerly, or that prisoners were inscribed as admissions more freely than had hitherto been the case. The short passage quoted from the Inspector-General below conveys the idea that dysentery continues to be very fatal to the people in the district of Jubbulpore. This may be so in the case of adults, but the death-rate from bowel complaints among the people as a whole was lower than the corresponding ratio of the preceding quinquennium.

Privation in the district increased up to the end of 1897, and so did the mortality, not from general diseases, but from this one disease—dysentery. Deaths from this disease showed highest in 1898, and is still continuing, and 1899 will not see the end of it. The victims of chronic privation linger on for months, and apparently years, but that terrible anasarca developes.

Coorg.—There is only one jail in Coorg, that of Mercara. The health of the prisoners was not so good as in 1897.

Madras.—The price of food-grains continued very high, and was higher during the first half of 1898 than at any time during the previous year. High prices seem to have led to an increase of crime, for the number of prisoners admitted into the jails was greater than in any of the ten years preceding. This state of matters was fortunately not accompanied by any unusual sickness and mortality, there having been almost a complete absence of cholera, and a reduction in the sick and death rates. There were, however, extraordinary sickness and mortality in the Rajamundry Central Prison. There was some division of opinion as to the presence of beri-beri in this jail; and the medical superintendent, Captain Fearnside, I.M.S., has written an account of the investigations which he carried out into the causes of sickness and mortality among the prisoners, and ably maintains his thesis that the cases which have been considered to be beri-beri were not cases of that disease but of severe malarial cachexia. Whatever was the cause of the unusual sickness there can be no difference of opinion that the proper measures of improvement have been undertaken in reducing the general population, segregating the sick, sending the cachectic to other jails, and generally ameliorating the sanitary conditions of the jail, including the food-supply; and it is satisfactory to know that matters are mending.

Mortality of prisoners and of troops compared.—A table is, as usual, here given to compare the mortality of prisoners in 1898 with that of soldiers. Taking the death-rate of European troops as unit, the death-rate of Native troops will be represented by 0·6, and the death-rate of prisoners by 1·3. The mortality of prisoners was comparatively high as regards bowel complaints, anæmia and debility, respiratory diseases, and tubercle of the lungs. Only from fevers was the European soldiers' mortality highest. The enormously greater liability of the prisoners to death from bowel complaints is well shown in the table. Taking the mortality of the Native troops from fevers as 1, that of the prisoners is 1·1, and that of the European troops 6·0. Taking the mortality of the Native troops from bowel complaints as 1, that of the European troops is 1·2, and that of the prisoners 10·4. Taking the mortality of the European troops from respiratory diseases as 1, that of the Native troops is 5·4, and that of the prisoners 6·4. While the liability of the Native soldiers to die from respiratory diseases was less than that of the prisoners, yet these diseases made up a larger percentage of the total deaths among Native soldiers than among prisoners. The chief cause of death among European troops was fevers, among Native troops respiratory diseases, and among prisoners bowel

complaints. Of course, for obvious reasons, too much must not be made of the comparison here instituted :—

Causes of Death.	Died per 1,000 of Average Strength.			Relative Liability in Percentages.				Percentage in Deaths from all Causes.

* Enteric, intermittent, remittent, and simple continued fevers.

General Population.

General Remarks.—In this report for 1897, the subject of Indian vital statistics was discussed at some length, and an attempt was made to indicate the outstanding peculiarities of the statistics obtained in the various provinces, so that it is unnecessary this year to do more than note the more important features of registration in 1898. Each year carries us further from the day on which the census figures were recorded, and each year the ratios calculated upon those figures must become less accurate. It is important, therefore, to remember that, in a province where the population is rapidly increasing, the mere rise of birth and death rates to figures which have some appearance of being correct may not be entirely due to improved registration. Still, there is abundant evidence that the accuracy of the figures collected is improving, although improvement is by no means uniform, and much remains to be done, even with the existing agency, in many provinces, particularly in the towns.

Births.—The following statement furnishes a brief epitome of the birth statistics in 1897 and 1898, shewing the numbers of the urban and rural populations under registration ; the numbers of children born, the millesimal birth-rates, with the average rates of the previous five years ; and the percentages of male to female births.

Birth Statistics.

Province.		Number of Municipalities and towns in which births were registered.	Number of rural circles in which births were registered.	Population under Registration. In Municipalities and towns.	Population under Registration. In Districts, excluding towns.	Population under Registration. Total.	Total number of births registered.	Ratio of births per 1,000 of population.	Highest birth-rate in any one district.	Lowest birth-rate in any one district.	Number of males born to every 100 females born.	Excess or deficiency of births compared with deaths.	Mean ratio of births per 1,000 during previous five years.

* Excluding Zamindaris of the Chattisgarh Division.

In 1898 the highest birth-rates were registered in the Punjab, 41·0 per 1,000, the North-Western Provinces and Oudh, 37·35, and Bengal, 35·79; and the lowest birth-rates were registered in Assam, 29·46 per 1,000, Madras, 27·4, and Coorg, 16·15.

In every province, except the North-Western Provinces and Oudh, the Central Provinces and Lower Burma, the birth-rates recorded in 1898 were lower than those recorded in the preceding year, and in only three provinces, Bengal, the North-Western Provinces and Oudh, and Lower Burma, were the rates higher than the averages of the previous five years. In only two provinces, however, Assam and Coorg, were the recorded births less numerous than the recorded deaths.

The percentage of male to female births ranged from 110·4 in the Punjab and 109·0 in Lower Burma to 105·2 in Berar and 104·3 in Madras.

Deaths.—The next statement gives details of the mortality in the different provinces in 1897 and 1898.

NOTE.—For population under registration, *see* preceding table.

The highest death-rates were 36·15, 31·44, and 31·05 per 1,000, registered, respectively, in Assam, the Punjab, and Coorg; and the lowest were 24·30, 23·4, and 21·0 per 1,000, registered in the Central Provinces, Berar, and Madras.

The year in most parts of the country was an extraordinarily healthy one, and in every province, except the Punjab and Lower Burma, the death-rates were lower, generally very much lower, than in the preceding year, while in every province save Madras, the Punjab, and Lower Burma, the rates were below the quinquennial averages. In the Punjab and Lower Burma the death-rates registered in 1898 were practically the same as those registered in 1897, the Punjab rate being very slightly in excess of the quinquennial average; and, although in Burma the rate registered in 1898 was considerably higher than the five-year average, the increase is largely due to improved registration. In Madras, registration continues defective, and the death-rate in 1898 was the same as the quinquennial average.

In every province the urban death-rates were higher than the rural. In every province, except Burma, the urban rates were lower than in 1897, and in every province, save the Punjab, the rural rates were also lower.

The following table exhibits the distribution of the mortality throughout the year :—

Statement showing the Deaths from all causes, according to Months, in the different Provinces of India during the year 1898.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.	RATIO OF DEATHS PER 1,000 OF POPULATION. 1898.	1897.
Bengal	189,699	134,963	153,833	149,699	153,927	116,010	118,325	159,565	151,780	179,253	195,794	185,650	1,888,468	26·57	32·94

* Excluding Zamindaris.

The mortality in every month of the year, except January, was less than in the preceding year, the total death-rate being only 27·13 per 1,000 in 1898 against 35·6 in 1897. The highest mortality occurred in the months of November, December, and October, in the order given, and the lowest in July, June, and February; the low mortality in June and July is noteworthy.

The following paragraphs contain a summary of the more important figures collected in the different provinces.

Bengal.—The total number of births registered in Bengal in 1898 was 2,543,701, or 82,143 less than in the preceding year; and the birth-rate, which declined from 38·03 per 1,000 in 1896 to 36·94 in 1897, fell still further to 35·79, which, however, is ·18 per 1,000 higher than the mean of the birth-rates recorded during the five years ending with 1897. The Sanitary Commissioner of the province ascribes the reduction in the birth-rate to the effect of the famine, "which lasted up to September, 1897, in some places, and to the high prices of food grains which prevailed almost up to the close of the year in several others." The Local Government does not, however, entirely endorse this view, and points out that, if the famine was the sole cause of the reduction in the birth-rate, there should be a reduction in the birth-rates of other provinces where famine prevailed, while in Bengal itself the reduction should be most distinctly marked in those districts most severely affected by famine. But this was not the case, for in the North-Western Provinces and Oudh, and in the Central Provinces, the birth-rates of 1898 were higher than those recorded in the preceding year, while in six of the fifteen districts, which were affected by famine in Bengal, the birth-rates of 1898 were higher than the birth-rates of 1897. It seems to be hinted that the postponement of marriages may have been the cause of the decline in the birth-rate in 1898, and an examination of the figures supports this view.

Famine may limit the natural increase of the people in several ways, three of which at least are obvious. If it is severe, it will exercise a directly unfavourable influence upon the fecundity of the very poor—it was noted in 1897 in Berar that women driven to the relief centres were rarely pregnant. Probably an even more potent factor is the absence from their homes in search of work of the heads of families. But even when famine is less severe, when the pinch of actual starvation is not felt, and few men are forced to leave their homes, a decline in the birth-rate is to be expected, for so far as caste usages will permit marriages will be deferred until the return of some degree of prosperity is assured. It is not easy, however, to determine the relative effect of these restraining causes, and in Bengal the rapid improvement of registration renders the comparison of the monthly birth-rates in 1898, with those of even recent years, difficult. If the monthly birth-rates from and including 1893 are examined, it will be found that a high rate in January is invariable—the maximum was recorded in that month in 1894; there is generally a fall in February, and a very distinct rise in March, after which the rates fall to a minimum in June, gradually ascending until September. In the last three months of an ordinary year, the rates are always high, and in one of the three, perhaps most often in December, the maximum of the year is generally reached.

In 1897 the monthly rates were fairly high, except in October and December, but in 1898 the rate in January was a low one, and the monthly rates remained low until August, after which they were much above the average until the end of the year, the rate recorded in November, 4·41 per 1,000, being the highest monthly rate recorded since 1892.

It is impossible to say how far the low rates in the first half of 1898 were due to the postponement of marriages, but there seems to be little room for doubt that the exaggeration of the normal rise in the latter part of the year was due to the consummation, when prosperity had returned, of numerous marriages which had been deferred during the persistence of hard times.

The highest district birth-rates were 43·59, 43·40, and 42·22 per 1,000, registered, respectively, in Murshidabad, Tippera, and Noakhali; and the lowest were 27·27, 26·87, and 13·98, registered in the 24-Parganas, Hooghly, and Calcutta. Calcutta is of course an urban district, but its birth-rate compares unfavourably with those of other towns, and with its own rate in 1897, which was 18·46. The falling off is attributed to the departure from the town of women for fear of plague. The average birth-rate in rural areas was 36·39, against only 24·02 in the towns. In some of the latter, notably Jangipur (44·82 per 1,000), Jamalpur, in Monghyr (44·05), and Jamalpur, in Mymensingh (42·11), the rates were high, but in the vast majority the rates were very low, the lowest being registered in Maniktala (9·61), Chittagong (8·84), and Jhalakati (8·45).

The causes believed by the provincial Sanitary Commissioner to account for the low rates in the towns are the following :—

(1) the preponderance of males in the urban population ;
(2) the presence of a large floating population ;
(3) the custom of women leaving the towns for their homes in the country for the purpose of being confined ; and,
(4) defective registration.

All these causes are, no doubt, more or less operative, not only in the towns of Bengal, but in most of the larger Indian towns, but it is of importance to discover how far each of the causes is operative, and what relation the fourth cause bears to the other three. In last year's report it was suggested in the case of Jhalakati, where the birth-rate of 1897 was only 2·11 per 1,000, that defective registration was mainly to blame for the low rate. Major Dyson has caused investigations to be made into the cause of the very low birth-rate in Jhalakati, and finds in the extraordinary condition of the small female population of the town cause for believing that registration there is as reliable as elsewhere in Bengal. From a statement given it seems that out of 399 females only 49 are married women capable of bearing children. But these figures are themselves suspicious. The census population of the town is 2,365, comprising 1,966 males and 399 females; and the number of females to which the investigation set forth in the statement relates is, very curiously, 399, exactly the same number of females that was recorded at the time of the census in 1891. But if registration in recent years was correct, the female population of Jhalakati, apart from immigrations, was only 351 in 1896, and if the same decline has been continued in 1897 and 1898, for which years there are no figures relating exclusively to females available, the female population in 1898 would be only about 341. The balance, of course, may have been made up by immigration, but this may be doubted in view of the fact that the statement showing the occupation of the female population includes neither infants nor children,

The provincial percentage of male to female births was 106, varying from 113 in Calcutta to 102 in Faridpur.

The total number of deaths registered was only 1,888,468, as compared with 2,341,632 in 1897, and the death-rate fell from 32·94 per 1,000 in that year to 26·57 in 1898, or 5·75 below the quinquennial average. The cause of the low death-rate was the exceptional salubrity of the year ; cholera mortality was only one-third of the average, and fevers and "dysentery and diarrhœa" were less fatal than usual.

The highest district death-rates were recorded in Noakhali, 40·99 per 1,000, Darjeeling, 39·73, and Chittagong, 36·99 ; and the lowest in Singhbhum, 17·28, Manbhum, 16·43, and the Sonthal Parganas, 15·33. In rural areas the average rate was 26·52 against 27·50 in the towns, among which the rates varied from 52·84 per 1,000 in Garulia, a small town in the 24-Parganas, which suffered severely from cholera, 49·54 in Malda, where fever was extraordinarily prevalent, and 44·72 in Serampore, where the deaths attributed to dysentery and diarrhœa were very numerous, to 12·82 in Cossipore-Chitpur, 11·26 in Raghunathpur, and 9·98 in Maniktala.

Among the various sects, Muhammadans had the highest death-rate, 29·53 per 1,000, and Christians the lowest, 17·69. The rate among "other classes," 17·89, was very little higher than that among Christians, while Hindus and Buddhists died at very similar rates, 25·51 and 25·61 per 1,000, respectively.

The largest number of deaths occurred in November, January, December, and October, and the smallest numbers in June and July.

Male infants died at the rate of 215·65 per 1,000, against 239·11 in 1897, and female infants at the rate of 170·28, against 194·14. The rates among boys and girls over one and under five were also lower than in 1897, 37·18 and 31·23 per 1,000, respectively, against 45·79 and 38·72, As usual, the male death-rates were higher in all age periods, the averages being 28·75 and 24·40 per 1,000 for males and females, respectively.

Port of Calcutta.—The number of European seamen who arrived in the Port during 1898 was 20,401, the average number in the Port being 1,232, or 30 more than in the preceding year. The total number of deaths among them was 28, equal to a death-rate, calculated on the average daily strength, of 22·72 per 1,000, against 33·27 per 1,000 in 1897.

Among the native floating population 122 deaths were reported during the year, which on a calculated average strength of 25,620 is equal to a death-rate of 4·76 per 1,000, as compared with 8·11 per 1,000 in 1897.

Assam.—The statistics from two mountain areas in Assam are treated separately from the general statistics of the province. These areas are the selected villages in the Garo Hills, with an aggregate population of 27,725, and Kohima, in the Naga Hills, with a population of 1,781. In the Garo Hills area, the birth-rate fell from 40·07 per 1,000 in 1897, to 36·25 in 1898, and the death-rate from 51·83 to 42·09. In Kohima the birth-rate, as in 1897, was 34·25 per 1,000, but the death-rate fell from 55·29 to 38·74. In the Brahmaputra and Surma Valleys, and in those portions of the Khasi and Jaintia Hills district which are under registration, the total number of births recorded was 147,889, or 15,728 fewer than in the preceding year, and the birth-rate fell from 32·59 per 1,000 in 1897, and a quinquennial average of 31·70 to 29·46. As in 1897, the highest district rates were recorded in Goalpara, Lakhimpur, and Sylhet, but the rates in 1898—38·18, 34·02, and 30·46, respectively—were very much lower than those recorded in the preceding year, which were 45·12, 35·17, and 35·17. At the other end of the scale, the same districts appear as in 1897, namely, Kamrup, Khasi and Jaintia Hills, and Nowgong, and in these districts also the rates recorded, 25·54, 24·55, and 18·66 per 1,000, were lower than in the preceding year. The average percentage of male to female births fell from 108·13 to 107·65, and ranged from 112·76 in Nowgong to 102·82 in Darrang, and 97·87 in the Khasi and Jaintia Hills.

The total number of deaths registered was 181,527 against 254,093 in 1897, and the death-rate, which in that year had reached 50·61 per 1,000, fell to 36·15, or ·38 per 1,000 less than the quinquennial average. Among the districts, the highest rates were 47·25 per 1,000 in Nowgong, 42·25 in Darrang, and 39·60 in the Khasi and Jaintia Hills; and the lowest were 31·78 in Cachar, 29·31 in Sibsagar, and 25·93 in Kamrup, where it is to be feared registration is very defective. In rural areas the average death-rate was 36·07 per 1,000, against an urban average of 40·04; the rates in the towns ranging from 67·39 in Golaghat and 61·54 in Hailakandi, to 20·54 in Maulvi Bazar.

Christians and Hindus died at nearly the same rate, 31·80 and 31·60 per 1,000, respectively, Muhammadans at the rate of 37·78, and "other classes" at the rate of 54·40.

The lowest monthly death-rates were recorded in February, March, and April; the highest in May, November, and December.

Male infants died at the rate of 198·04 and female infants at the rate of 181·30 per 1,000; and boys and girls over one and under five at the rates, respectively, of 37·71 and 36·12. In all age periods, save 20–30, the male rates were the higher, the averages being 37·58 for males, and 34·63 for females.

North-Western Provinces and Oudh.—The year 1898 was an exceptionally healthy one in the North-Western Provinces and Oudh; the birth-rate was not only higher than the quinquennial mean, but was higher by ·36 per 1,000 than the average of the five years ending with 1895, while the death-rate, with the exception of that registered in 1893, was the lowest on record. The total number of births registered was 1,751,725 against 1,458,947 in 1897, and the birth-rate was 37·35 per 1,000 as compared with 31·10 in the previous year, and 36·41 the quinquennial mean. Among the districts, the highest rates registered were 53·93 per 1,000, in Bulandshahr, 50·48 in Etah, and 49·26 in Budaun, all western districts; and the lowest were registered in Jaunpur 27·34, Mirzapur 26·12, and Azamgarh 25·99, all districts in the east of the province. In the municipalities the rates ranged from 57·32 in Sikandarabad, to 7·41 in Mussoorie. In every district, except Naini Tal, births were more numerous than deaths, although in Mainpuri and Mirzapur the excess was small. The percentage of male to female births, which in 1897 was 108·98, fell to 108·05, and ranged from 120·34 in Dehra Dun to 103·38 in Garhwal.

The number of deaths registered was 1,284,319, or 613,273 fewer than in the preceding year, and the death-rate, which was 40·46 in 1897, and averaged 33·90 in the previous five years, fell to 27·38. The highest district death-rates were 41·59 per 1,000 in Naini Tal, 41·49 in Bareilly, and 37·03 in Pilibhit; and the lowest were 22·05 in Azamgarh, 21·03 in Hardoi, and 19·11 in Gorakhpur. In rural areas the average death-rate was 26·94 per 1,000 as compared with 33·41 in the towns in which the rates ranged from 48·92 in Kashipur in the Terai, to 16·93 in Sahtawar. In 31 of the 104 municipalities the deaths were more numerous than the births, as compared with 76 in the preceding year.

Among the various sects, Muhammadans had the highest death-rate, 27·49, followed very closely by Hindus with 27·41; Christians died at the rate of 11·94 per 1,000, and "other classes" at the rate of 18·39.

The highest monthly death-rates occurred in October, November, December, and September in the order given, which correspond roughly with the months when the birth-rates were highest, namely October, December, September, and November. The lowest death-rates occurred in July, March, and February, and the lowest birth-rates in April, June, and May.

Among male infants the death-rate was 227·74 per 1,000 and among females 210·46, against 262·97 and 255·10 in 1897. The mortality among children between the ages of one year and five years, shows a much larger proportional reduction from 73·64 and 72·78 per 1,000 among boys and girls, respectively, in 1897, to 44·63 and 44·48 in 1898. At all age periods, except those between 15 and 20, and 20 and 30, males died at a higher rate than females, the average being 27·65 per 1,000 against 27·09.

Punjab.—The number of births registered in the Punjab in 1898 was 841,869 as compared with 874,623 in the preceding year ; and the birth-rate was 41·0 per 1,000 as against 42·6 in 1897, and 41·7 the quinquennial mean. The Sanitary Commissioner hazards the suggestion that the scarcity of 1897 was the cause of the decline of the birth-rate of 1898, but the Local Government points out that in the districts of Gujrat and Hissar, where famine was most severe in 1897, the birth-rates of 1898 were higher than those of the former year ; and, although the argument based upon this is somewhat discounted by the fact that the rates in these districts in 1898 were below the quinquennial averages, it does not seem probable that the famine accounts for much of the decline in the provincial average. If the rates registered in the districts in 1898 are compared with the averages in the same districts during the previous five years, it will be found that there was a great falling off in all the districts of the Derajat Division, especially in Dera Ismail Khan, but in the other divisions, the rates rose in some districts and fell in others, and there was no general fall or rise. Among the districts, the birth-rates ranged from 53·8 per 1,000 in Gujranwala to 21·18 in Simla ; from 53·4 in Jhang to 29·8 in Peshawar, and from 53·0 in Gurgaon to 30·6 in both Dera Ismail Khan and Dera Ghazi Khan. In Simla the sex distribution of the population accounts for a low birth-rate, but the extreme divergences elsewhere suggest defective registration. In the Derajat Division, for instance, there were fewer births than usual and more deaths. The unhealthy season caused the increased deaths, and may explain also the decrease in the number of births, not necessarily on account of any deterioration of the reproductive energy of the people, but because the presence of sickness would deter many of them from registering births. The percentages of males born to females, which in 1897 was 110·5, fell to 110·4, and ranged from 125·1 in Dera Ghazi Khan to 104·8 in both Delhi and Kangra.

The number of deaths registered in 1898 was 638,124, or 103 fewer than in the preceding year, the death-rates being practically the same in both years, 31·05 per 1,000, which is slightly less than the quinquennial mean of 31·30. Although the average death-rate of the province in 1898 was not far from the quinquennial average, the death-rates in the districts, except those in the Peshawar Division, show great divergencies from the quinquennial averages recorded in them. In all the districts of the Rawalpindi and Derajat Divisions, except in the Rawalpindi district itself, the rates in 1898 were above the average ; while in all the districts of the Delhi and Jullundur Divisions, except Gurgaon and Ferozepore, the rates were below the average. In the Lahore Division the lowest district death-rate was recorded, 21·3 per 1,000 in Montgomery, while in the same division the highest rate, with the single exception of Dera Ismail Khan (40·1), was also recorded, namely, 39·4 in Jhang. Other extreme rates were 37·9 in Karnal, and 21·6 in Simla, and 21·4 in Hazara.

The average death-rate in rural areas was 30·82 per 1,000, against 33·05 in the towns, in which rates ranged from 53·86 in Dera Ismail Khan, 53·16 in Bannu, and 52·04 in Gurdaspur, to 17·25 in Montgomery, 17·19 in Talamba in Multan, and 13·78 in Abbottabad.

By far the highest death-rate among the various sects was 79·61 per 1,000 registered among "other classes ;" but it is explained that this is not a real rate, and is due to errors in classifying. Muhammadans died at the rate of 31·19 per 1,000, and Hindus at the rate of 30·86 ; while far behind both come Native Christians with a death-rate of only 19·54.

As in the preceding year, the lowest death-rates occurred in the months of February, March, and April, and the highest in October and November.

Male infants died at the rate of 215·19 per 1,000 and females at the rate of 210·09, as compared with 223·02 and 228·02 in the preceding year. Boys and girls between one year and five years of age died, respectively, at the rates of 63·04 and 68·57 per 1,000, as against 58·4, and 66·76 per 1,000 in 1897. At all age periods, save in infancy and 40–50 and

50–60, the female death-rates were the higher, the averages being 29·89 per 1,000 for males, and 32·36 per 1,000 for females.

Central Provinces.—With the exception of the year 1894, when there was a slight rise the number of births recorded in the Central Provinces has declined year by year since 1892. In 1897, the total number registered was only 254,973, and it is satisfactory to note in 1898 a rise to 284,176, equal to a birth-rate of 29·91 per 1,000, as compared with 26·83 in the preceding year, and a quinquennial average of 33·80. The highest district birth-rates were 45·54 per 1,000 registered in Nimar, 45·01 in Sambalpur, and 39·63 in Chhindwara ; while the lowest were 26·17 in Seoni, 24.75 in Balaghat, and 22·18 in Saugor. In six districts—Nimar, Burhanpur, Betul, Nagpur, Wardha, and Chanda—the births were fewer than in the previous year ; but in only two districts, Saugor and Damoh, where scarcity still lingered, were the births less numerous than the deaths. The monthly distribution of births during 1898 is interesting. In the first seven months of the year, the birth-rates were much below the normal, far fewer indeed than in the corresponding months of 1897, and the usual rise in March and April was hardly visible ; but in August there was a rise, and in September the total had reached a figure in excess of any recorded in September since 1891. In October the number of births was almost exactly double that recorded in the October previous, and was the highest monthly total on record ; and exceptionally high figures were registered during the remaining months of the year. The percentage of male to female births was 106·69, ranging from 111·14 in Nimar to 101·85 in Raipur.

The number of deaths registered was 230,907 and the death-rate, which is the lowest on record, was only 24·30 per 1,000, as compared with 69·34 in 1897, and an average of 44·06 in the previous five years. Among the districts the highest rates registered were 33·64 per 1,000 in Nimar, 33·18 in Burhanpur, and 30·48 in Damoh—all considerably lower than the lowest rate recorded in 1897, with the single exception of Sambalpur which escaped the direct effects of famine. The lowest district death-rates in 1898 were 21·36, 20·69, and 19·72 per 1,000 recorded, respectively, in Raipur, Bilaspur, and Mandla. In rural areas the average rate was 23·98 per 1,000 as compared with 27·62 in the towns, where the death-rate ranged from 55·66 per 1,000 in Burha in Balaghat, and 44·96 in Khurai in Saugor, to 15·07 in Warora in Chanda, and 14·0 in Rajin in Raipur.

The provincial Sanitary Commissioner warns us that there is a doubt regarding the general accuracy of class registration, the results of which in 1898 shew the Hindus with the lowest death-rate, 22·44 per 1,000, and "other classes" with the highest, 34·07, while Muhammadans come in between with 27·12. In 1897 the rates were Muhammadans 52·61, Hindus 59·72, and "other classes" 126·23.

The largest numbers of deaths were recorded in the months of January, October, and December, and the smallest in July, June, and August.

Infantile mortality was unusually low, male and female infants dying at the rates of 240·11 and 205·45 per 1,000, as compared with the enormous rates of 403·00 and 356·11 registered in the preceding year. Boys and girls over one year and under five years of age died at the rate of 26·13 and 22·37, respectively, as compared with 79·64 and 63·78 in 1897. As seems to be invariable in the Central Provinces, the male death-rates were the higher at every age period, the average death-rates being 25·80 per 1,000 for males, and 22·80 per 1,000 for females.

Berar.—The number of births registered in Berar in 1898 was 89,414 as compared with 113,364 in the preceding year, and the birth-rate fell from 39·7 per 1,000 to 31·3, or 6·3 per 1,000 below the quinquennial mean. The highest district birth-rates were 33·6 and 33·2 per 1,000, registered, respectively, in Akola and Ellichpur, and the lowest were 30·5 and 28·4 in Amraoti and Basim. The number of births recorded exceeded the deaths in every district, the excess reaching 10·4 per 1,000 in Wun. The average percentage of male to female births, which in 1897 was 106·7, fell to 105·2, varying between 107·2 in Buldana and 103·0 in Amraoti.

The number of deaths fell from 150,222, in 1897, to 66,806, and the death-rate from 62·6 to 23·4 per 1,000, which is 20·8 per 1,000 below the average of the previous five years and one of the lowest death-rates recorded in Berar. In only two of the districts, Wun (20·4) and Basim (21·0) were the death-rates lower than the provincial average ; in the remaining districts the rates ranged from 25·1 in Akola to 24·0 in Amraoti. In rural areas the average death-rate was 23·1, against 25·5 per 1,000 in the towns, in which the extremes registered were 34·7 in Nandura, in Buldana, and 15·6 in Umarkhed, in Basim.

Christians and "other classes" died at the rates of 22·6 and 31·6 per 1,000, respectively; Muhammadans and Hindus at the rate of 23·4 and 23·1. The monthly mortality was highest in November and December, and lowest in June.

Male and female infants died at the rate of 194·8 and 166·8 per 1,000; and boys and girls, between one year and five years of age at the rates, respectively, of 46·0 and 41·0. In the age periods, 10–15 and 20–30, the female death-rates were the higher, at all other periods males died at the greater rate, the averages being 24·1 per 1,000 among males, and 22·7 per 1,000 among females.

Madras.—A falling off in the number of recorded births from 935,845, in 1897, to 911,742 reduced the birth-rate from 28·7 per 1,000 to 27·4, or 1·1 per 1,000 below the quinquennial average. As in the preceding year, the highest district birth-rates were recorded in Madras (41·5 per 1,000), Chingleput (35·7), and Kistna (34·2), but the rates, especially in the case of Chingleput, were lower in 1898 than in 1897. The lowest district rates were 22·9, 22·7, and 18·6 registered, respectively, in Ganjam, Madura, and Malabar; the decline in the birth-rate in Madura, where the average is 29·4, being due to the inclusion in the district statistics of figures from certain zamindaris. In rural areas the average birth-rate was 26·9 per 1,000, against 33·0 in the towns, among which the highest rates recorded were 54·5 in Vaniyambadi and 49·0 in Periyakulam. The percentage of male to female births rose from 104·0 in 1897 to 104·3, and ranged from 112·8 in Ganjam to 95·8 in the Nilgiris.

The number of deaths registered in 1898 was 699,108 or 128,417 fewer than in the preceding year, and the death-rate, which had reached 25·4 per 1,000, fell to 21·0, the same as the quinquennial average. By far the highest district death-rate was recorded in Madras, 45·2 per 1,000, and this was followed by 30·9 and 25·9 in the Nilgiris and Tanjore, respectively. The lowest rates were recorded in Malabar, 17·5, per 1,000, Godaveri 16·7, and Madura 15·6. The average recorded death-rate in rural areas was only 20·3 per 1,000 against 29·8 in the towns, where the rates ranged from 45·2 in Madras and 39·3 in Guntur and in Ootacamund, to 8·1 in Samalkote in the Godaveri district.

Among the different sects the highest death-rate was 21·3 per 1,000 registered for Hindus; Muhammadans followed with 18·9, then Native Christians 16·2, and lastly "other classes," 14·1.

The highest monthly death-rate was recorded in January (2·4); there was a considerable fall in February (1·8) and in March (1·6); the rates remained the same (1·5) during the next three months, to rise again in July, August, and September (1·7); there was a fall in October (1·6), but this was followed by a rise in November (1·9) and December (2·1).

Male infants died at the rate of 140·9 per 1,000, and females at the rate of 116·0; boys and girls, between one year and five years of age, died at the rates of 25·9 and 24·1, respectively. In the age period, 15–20, females died at a higher rate than males, 11·4 per 1,000 against 9·3, and in the next age period, 20–30, the sexes died at the same rate (10·3), but in all other age periods the male rates were higher, the average being 21·9 per 1,000 against 20·1.

Coorg.—The number of births registered in 1898 in Coorg was only 2,795, a smaller number than in any year since 1890, and the birth-rate of the year was 16·15 per 1,000, as compared with 20·24 in the preceding year, and a quinquennial average of 24·18. The rates in the various districts ranged from 19·05 in Kiggatnad to 11·58 in Mercara; and and in all the five districts the recorded births were less numerous than the deaths. The average birth-rate in the towns was only 7·67 per 1,000. The percentage of males to females born rose from 100·74 in 1897 to 107·34, and ranged from 117·48 in Nanjarajapatna to 97·10 in Yedenalknad.

Although deaths were much less numerous in 1898 than in 1897, 5,440 against 8,658, the death-rate was a high one for Coorg, 31·44 per 1,000, against an average of 31·07 in in the previous five years, which include the record death-rate of 50·03 per 1,000 in 1897.

The district death-rates varied between 37·63 per 1,000 in Nanjarajapatna and 24·13 in Kiggatnad. The average rate in rural areas was 30·42, against 41·78 in the towns. The latter are all very small, and the death-rates in some of them are enormously raised by the inclusion in the statistics of the deaths in the dispensaries of coolies, *e.g.*, the death-rate in Virajendrapett was 73·73 per 1,000, but of the 328 recorded deaths no less than 206 occurred in hospital, and 191 of the 206 were coolies on their way to or from the coffee estates. Similarly, if the deaths of coolies are deducted from the total number registered in Mercara, the death-rate of the town is reduced from 30·85 per 1,000 to 21·32.

Among Hindus, who form the vast majority of the population, the death-rate was 30·17 ; among Muhammadans it was 32·53, and among the smaller number described as "other classes" it was 83·50. The year began with a high death-rate in January ; there was a fall in February, but in March the mortality rose, to fall again in April, after which it rose to a maximum in June, falling month by month until December, when it again rose.

The death-rate among infants was 187·2 per 1,000 among males, and 157·08 among females, against 359·85 and 331·37, respectively, in the preceding year ; among boys and girls over one year and under five years of age, the rates were 35·26 and 30·50, against 77·06 and 78·41 in 1897. In the age periods, 10–15, 40–50, and 50–60, the female death-rates were the higher, and the average death-rates were 32·11 among males, and 30·59 among females.

Bombay.—The number of births registered in the Presidency of Bombay, including Sind, again shows a considerable decline from 691,847 in 1896, and 629,693 in the following year, to 582,371 in 1898. The birth-rate in 1898 was only 30·94 per 1,000, against 33·46 in the preceding year, and a quinquennial average of 35·28. The highest district birth-rates were registered in the Panch Mahals, 42·33 per 1,000, Khandesh 40·74, and Broach 40·49 ; the lowest in Ratnagiri, 24·52 per 1,000, Kanara 23·76, Hyderabad 16·96, and Bombay City 13·08. In rural areas the average birth-rate was 31·91 per 1,000, against only 24·05 in the towns, where rates ranged from 64·97 in Borsad, 52·0 in Kapadvanj, both in Kaira, and 50·59 in Nandurbar in Khandesh, to 12·64 in Sholapur, 12·27 in Ahmednagar, and 10·83 in Poona ; the low rates in the two last being ascribed to the exodus on account of plague.

The percentage of male to female births fell from 108·42 in 1897 to 108·19, ranging from 137·27 in Hyderabad to 101·95 in Dharwar. The smallest number of births was recorded in the month of February, and the monthly totals were much below the normals until August, when the number was about the average; but in the succeeding months the numbers born were far above the average, the maximum being recorded in October.

The total number of deaths registered was 548,825, or 201,091 fewer than in the previous year, so that in spite of the presence of plague, the death-rate fell from 39·84 per 1,000 to 29·16, which is not only lower than the mean of the previous five years, 31·92, but is lower by 1·29 per 1,000 than the mean of the five years ending with 1896, which include no year of exceptional mortality. The highest district death-rates were 64·03, 63·81, and 41·77 per 1,000 registered, respectively, in the City of Bombay, Dharwar, and Belgaum ; and the lowest 17·27, 14·58, and 11·04 per 1,000 in Upper Sind Frontier, Thar and Parkar, and Hyderabed. In rural areas the average death-rate was 26·55, against an average of 47·88 in the towns, among which the highest rates registered were 106·76, 93·25, and 69·08 in the plague-stricken towns of Belgaum, Gokak, and Hubli.

The highest death-rates were recorded among Parsis and Christians, 32·54 and 32·22 per 1,000, respectively, and the lowest rate among "other classes" 7·25. Hindus died at a much higher rate than Muhammadans, 30·71 per 1,000 against 23·76.

The monthly death-rates fell fairly regularly from January (2·65) to a minimum in June (1·61), then rose rapidly to a maximum in October (3·21), falling slightly to the end of the year.

Male infants died at the rate of 157·22 per 1,000, and females at the rate of 135·50 ; children between one year of age and five years at the rates of 42·84 among boys and 40·50 among girls. In the age periods 5–10, 10–15, 15–20, and 20–30, females died at the higher rate, the averages being 29·66 per 1,000 among males, and 28·63 among females.

Burma.—A slight reduction has been made in the population referred to in the registration returns of Lower Burma, by the exclusion from them of certain inaccessible tracts of the Toungoo and Mergui districts, which are patrolled only at irregular intervals. The average birth and death-rates in these tracts in 1898 were registered as 18·94 and 11·77 per 1,000 ; and, although these may be much understated, since, however, the aggregate population of the tracts is only 17,163, but little difference in the provincial returns results from its exclusion. In Lower Burma, the total number of births registered in 1898 was 153,838, more than 10,000 in excess of the total of the preceding year, and the birth-rate was 34·11 per 1,000, as compared with 31·82 in 1897, and 29·36 the quinquennial mean. Hitherto, 32·27 per 1,000, the birth-rate registered in

1896, has been the highest on record, and the increase of nearly 2 per 1,000 in 1898 affords evidence that the attention given in recent years to the improvement of registration in Burma is bearing fruit. But a good deal remains to be done as a comparison of the ratios obtained in the districts shows. In Myaungmya, Mergui, and Pegu, the birth-rates were respectively, 45·24, 45·09, and 41·49 per 1,000. while in Prome, Akyab, and Rangoon they were only 29·80, 28·58, and 18·77. The Rangoon district is entirely urban, and the male population is greatly in excess of the female, and there is a similar excess of males in the Akyab district; but in Prome, if the proportion of the sexes determined at the census has been maintained, there is a considerable excess of females, while in Myaungmya, Mergui and Pegu, males are the more numerous. The average birth-rate in rural areas was 35·34 per 1,000, very nearly 10 per 1,000 higher than the average of 25·78 registered in the towns, in which the rates ranged from 50·05 in Kawkareik to 15·02 in Akyab. In the province as a whole, 109 boys were born for every 100 girls, the percentages ranging from 115 in Rangoon Town district to 103 in Bassein.

The number of deaths registered was 117,856, and the death-rate was 26·13 as compared with 26·26 in the preceding year, and 23·52, the mean of the previous five years. The district death-rates varied between 43·39 per 1,000 in Rangoon Town district, where alone the deaths exceeded the births, to 18·40 in Mergui. In rural areas the average death-rate was 25·09, or about 8 per 1,000 less than the average in the towns which was 33·10, ranging from 43·39 in Rangoon and 41·91 in Pegu to 17·38 in Sandoway.

Among the different sects, by far the highest mortality was registered among the Hindus, who died at the rate of 37·51. It is explained that "this is due to the bulk of the Hindu population being made up of coolies, who, from the nature of their occupation, are specially liable to early breakdown. In towns they huddle together in overcrowded rooms, and in the district live in squalid huts not raised above the ground as Burman houses are." These conditions no doubt conduce to to a high death-rate, but as there can be proportionately few infants and young children among the coolies, they do not seem sufficient to account for a rise in the mortality among Hindus from 20·99 per 1,000 in 1895 to 25·15, 31·51, and 37·51 in the three succeeding years. Christians had the lowest death-rate, 16·25 per 1,000, after whom came Muhammadans with 23·60, "other classes" with 25·89, and Burmese with 26·08.

The lowest mortality occurred in March and April, and the highest in July and August.

Among male infants the death-rate was 287·35 per 1,000 living, as compared with 193·96 among females; boys and girls between one year and five years of age died, respectively, at the rates of 35·92 and 30·43 per 1,000. The death-rates of children have shown a progressive increase in recent years, due no doubt to the increase in the actual population, while that on which ratios are calculated remains the same. At all age periods, save between 30 and 40, the male death-rates were the higher, the average being 27·92 per 1,000 among males, and 24·12 per 1,000 among females.

In Upper Burma registration throughout 1898 was limited to nine towns with an aggregate population of 280,297, comprising 139,489 males and 140,808 females. The number of births registered was 9,546, or 34·06 per 1,000 of the population, but the variation in the rates was considerable, from 45·41 in Yamethin to 28·34 in Monywa, and 11·76 in Pagan. The average death-rate was 29·71, ranging from 36·44 in Pyinmana, to 16·63 in Pagan. The registration of births and deaths has been extended to three more towns, making twelve in all, and arrangements were completed to introduce the registration of deaths into selected districts.

History of Chief Diseases.

Cholera.

There is no discovery regarding the etiology of cholera to chronicle. In the greater part of India, as the following paragraphs will show, the disease remained in comparative abeyance throughout the year, a year of remarkable prevalence being succeeded by one of singular absence of the disease. We may congratulate ourselves on the fact, but we cannot explain it.

Anti-cholera inoculations were continued at the coolie-depôt at Purulia in Bengal, but it is not possible to say how far the inoculation was protective as there are no complete statistics, the Chief Commisioner of Assam having decided that it would be inexpedient to prescribe for preparation by the managers of tea-gardens of the half yearly returns to which allusion was made in this Report for 1897. If any conclusion is permissible from such figures as are available, it is decidedly in favour of the operation.

The disinfection of wells with permanganate of potassium, as recommended by Mr. Hankin, has become almost a routine practice in many parts of India in the presence of cholera. So far there is nothing on record to prove the utility of the procedure, but general impressions are almost universally favourable to it.

In 1897 there were 555,035 deaths recorded as due to cholera, and the death-rate, calculated upon the whole population under registration, was 2·55 per 1,000. In 1898 the number of deaths fell to 152,703, fewer than in any year since 1880, and less than the number registered in an average year in Bengal alone. The death-rate in 1898 in the country generally averaged ·70 per 1,000, and in every province, except Madras, the death-rate was much below the average. In Madras the deaths recorded numbered 65,444, a very striking contrast to the number, seven, registered in the adjoining Central Provinces. In the Punjab only 33 deaths were recorded, in Rajputana and in Hyderabad only six, in Central India only two, and in Berar not a single one.

The statement below shows the total numbers of deaths attributed to cholera in every province in India in each year from 1877 onwards :—

Statement showing the deaths from Cholera in the different Provinces in India from 1877 *to* 1898.

YEAR.	Bengal.*	Assam.	N.-W. P. and Oudh.	Punjab.	Central Provinces.	Berar.	Rajputana.	Central India.	Bombay.	Hyderabad.	Madras.	Mysore.	Coorg.	Lower Burma.	Ajmer-Merwara.

* Excluding Calcutta from 1877 to 1892.
† Including 30 deaths in Cantonments.
‡ Statistics not available.
§ Excluding Zamindaries.

From the following statement of the seasonal distribution of the disease it will be seen that by far the largest number of deaths occurred in January ; there was a great fall in the mortality in February, continued in a slight degree in March, followed by a rise in April. The mortality again declined in May, and in June there was a remarkable fall, the low figures recorded in that month becoming gradually lower, except for a slight rise in

August, till the minimum was reached in October; a slight rise in November was followed by a great rise in December :—

Statement showing the Deaths from Cholera registered in the different Provinces by Months during the year 1898.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.	RATIO OF DEATHS PER 1,000 OF POPULATION. 1898.	1897.

* Excluding Zamindaries. † Including Cantonments. ‡ The total deaths numbered 7 only.

Bengal.—In Bengal in 1898 the number of deaths registered as due to cholera was 65,020, and it is necessary to go back for eighteen years to find so low a cholera mortality. In 1880 the number of deaths was only 39,643, but only twice since,

in 1881 when the total was 79,180, and in 1883 when it was 90,439, have the totals been less than a hundred thousand, and in most years they have been much more. The cholera death-rate in 1898 was ·91 per 1,000, less than a third of the rate of the preceding year, which was 2·76, and a little more than a third of the quinquennial average of 2·71. The low mortality is attributed by the provincial Sanitary Commissioner, chiefly to "the almost normal rainfall of the year, and the satisfactory agricultural outturn almost everywhere." Although in every district, with the exception of Chittagong and Purnea, the mortality was below the average, the disease was entirely absent from only one district, Palamau. It was absent from 130 of the 710 circles of registration, and was present in epidemic form in only eighteen. The highest district death-rates were 7·92 per 1,000 registered in Chittagong, 3·15 in Balasore, 2·70 in Tippera, and 2·20 in Bhagalpur. In Chittagong the high mortality seems to have been due to the conditions following the occurrence of the cyclone of October 1897. The disease was exceedingly prevalent in this district in January, it declined considerably in February, and still more in March, when the number of deaths fell to 566 ; a further decline to 128 occurred in July, after which cholera almost disappeared from the district.

In Puri, where the mortality, 9·57 per 1,000, was highest in 1897, the death-rate fell in 1898 to ·45, a fall which is attributed to "the improved sanitary condition of the place and to the opening of the East Coast Railway, which facilitated the rapid dispersion of pilgrims who congregate in Puri on the occasion of religious festivals several times a year." It may be noted that although deaths occurred in Puri in every month of the year, serious mortality was limited to the first four, and that the rapid dispersal of pilgrims did not lead to an outbreak of the disease elsewhere.

In the rural areas the average death-rate was ·91 per 1,000 as compared with ·94 in the towns. No less than 39 of the latter escaped the occurrence at any rate of fatal cases, and in other 24, deaths were limited to one or two. In a few small towns the mortality was heavy, notably in Garulia 15·15 per mille, Madaripur 6·60, Bajitpur 5·95, and Narayanganj 5·47. In Balasore the death-rate was 7·60 per 1,000, in Patna 1·60, and in Gaya 2·32.

Taking the province as a whole, the greatest mortality occurred in April, January, and May, and the least in September, August, and July. In the main divisions of the province there were, as usual, variations in the seasonal prevalence of the disease. The maxima in Bengal Proper occurred in January, April and May ; in Behar, in April and May ; in Orissa, in March and April ; and in Chota Nagpur in March. The minima were recorded in Bengal Proper, in September, August and October ; in Behar, in January and February ; in Orissa, in September and November ; and in Chota Nagpur in December.

Three cases and two deaths occurred among the European seamen in the Port of Calcutta, equal to a death-rate, calculated on the average strength, of 1·62 per 1,000, by far the lowest rate recorded, at any rate in recent years.

Assam.—The number of deaths attributed to cholera in Assam was 11,149, equal to a death-rate of 2·22 per 1,000, about one-third of the rate in the preceding year and rather more than half the quinquennial average of 4·17. In every district the death-rates were much lower than in 1897, and in every district they were below the five years' average. The highest rate was 3·39 per 1,000 registered in Kamrup, and this was followed by the rates registered in the Surma Valley districts, 2·57 in Cachar, and 2·50 in Sylhet. The lowest rates registered were ·54 and ·55 in Nowgong and the Khasi and Jaintia Hills respectively ; in the remaining districts the rates varied between 1·86 in Goalpara and 1·48 in Lakhimpur. In rural areas the average death-rate was 2·23 per 1,000 against 1·87 in the towns. Among the latter there were six, including Shillong, in which no death occurred, and rates were high in only Karimganj 6·57, Habiganj 5·77, Dhubri 4·35, Sunamganj 3·50, and Silchar 3·19.

Among immigrant coolies the numbers of deaths, 26 on board steamers, and 58 at the depôts, were smaller than for years past ; but on the tea-gardens the cholera death-rate was higher than among the general population. There were in all 1,627 deaths on the gardens, equal to a death-rate of 3·57 per 1,000 of the census population, and to 2·53 per 1,000 of the population in 1898 calculated upon the immigration returns.

In the province as a whole, the greatest mortality from cholera occurred in May, June, and April and the least in November and December. The maxima in the Surma Valley occurred in May and June, and in the Brahmaputra Valley in April and May, the minima occurring, respectively, in November and September and in December and November.

North-Western Provinces and Oudh.—In these provinces the mortality from cholera was unprecedently low, only 2,508 deaths were recorded, the smallest number since the

introduction of trustworthy registration in 1871. The death-rate was ·05 per 1,000 as compared with ·94 in the previous year, and the quinquennial average of 1·51. No less than six districts seem to have escaped the disease altogether, and in a good many others, notably those of Meerut Division, the few scattered deaths that occurred may not have been due to true cholera. The immunity of the rural population, among whom the death-rate was ·05 per 1,000, may be gauged from the fact that from only 516 out of 107,132 villages was the occurrence of deaths reported. Among the population of the larger towns, 265 deaths in all were recorded, equal to a death-rate of ·08 per 1,000. In only two of the towns was the rate in excess of 1 per 1,000, Tanda 1·67, and Rudhauli 8·33, situated in the districts, respectively, of Fyzabad and Bara Banki, where the highest district rates ·43 and ·39 per 1,000 were recorded. The maximum prevalence of the disease occurred in November and the minimum in March.

Punjab.—Save for an outbreak in April, resulting in about 30 deaths in the Umballa Cantonment, the Punjab was practically free from cholera, only three cases being reported, two in April, in the town of Rewari, in the Gurgaon District, and one in Umballa City in September.

Central Provinces.—After the severe epidemics of 1896 and 1897, in which, respectively, 52,985 and 57,131 deaths were registered, the total cholera mortality in the Central Provinces fell to seven deaths. The incidence of cholera in these provinces is occasionally slight, but nothing approaching the low mortality of 1898 has been recorded since 1874, when the deaths numbered only 14. Of the seven deaths which were registered in 1898, four occurred in the district of Balaghat, two in April and two in July; two in Nagpur in May and July, and one in Saugor in February.

Berar.—After occasioning the comparatively high death-rates of 4·2, 4·3, and 3·5 per 1,000 in 1895, 1896, and 1897, respectively, cholera disappeared from the province in November 1897, and in 1898 not a single death was recorded as due to the disease. Although cholera has been continuously present in Berar for the last seventeen years, its complete abeyance is not unknown; in 1880 only one death was recorded—in Buldana; in 1874 only two, also in Buldana, and in 1873 no death was recorded.

Madras.—The total number of deaths attributed to cholera in Madras in 1898 was 65,444, and the death-rate fell from 4·4 per 1,000 in the preceding year to 2·0, as compared with a quinquennial average of 1·8. The death-rates were very high in the neighbouring districts of Tanjore (6·7), Trichinopoly (5·5), and South Arcot (5·2). These are irrigated districts, as also is Kistna, where the next highest rate, 2·9 per 1,000 was recorded. In Nellore, which adjoins Kistna on the south, the cholera death-rate was 2·8, but this district was affected by famine during the year. In thirteen districts the death-rates from cholera were under the average; and in Ganjam only 46 deaths were registered, in Anantpur only nine, and in the Nilgiris only one.

Although 29 of the towns escaped altogether, the average urban death-rate was 2·1 per 1,000 or ·1 per 1,000 higher than the rural rate. Among the towns some of the death-rates were very high, notably in Ramnad (24·5) and Palni (14·4), both in Madura; in Tiruvallur (11·3) in Tanjore, in Arcot (8·1), in Chidambaram (7·7) in South Arcot, and in Trichinopoly (7·3).

The largest numbers of deaths occurred in January (18,113), February (9,052), and December (6,649), and the smallest numbers in October (1,636) and June (1,984).

Coorg.—Only eight deaths from cholera were registered in Coorg, equal to a death-rate of ·05 per 1,000 of the population, against ·61 in 1897, and an average in the previous five years of ·20. The deaths occurred in February and March, seven in the Padinalknad taluk and one in the Mercara taluk.

Bombay.—The number of deaths registered as due to cholera in Bombay was 4,368, and the death-rate, which is the lowest since 1890, was ·23 per 1,000 against 3·03 in 1897, and a quinquennial average of 1·63. No less than 4,054 of the deaths occurred in the district of Dharwar, where the death-rate from cholera was 3·86 per 1,000. There were 104 cases in the City of Bombay, 97 in the Belgaum district, 79 in Kanara, and 15 in Kolaba. In the remaining districts there were only a few scattered cases; Khandesh, Nasik, Ratnagiri, Surat, Broach, Kaira, Panch Machals, and the districts in Sind escaping altogether—the Sind districts for the second year in succession. The town of Gadag-Betgeri in Dharwar suffered severely, 342 deaths, giving a death-rate of 14·36 per 1,000; and the next highest urban death-rate was 2·25 in Ranebennur in the same

district. Only 536 deaths occurred in the towns, and the urban and rural death-rates were identical. The greatest prevalence of the disease occurred in August and the least in December.

Burma.—The number of cholera deaths registered in Lower Burma in 1898 was 2,972, and the death-rate was ·66 per 1,000, as compared with 1·89 in the previous year, and a quinquennial average of 1·17. In every district save four, Akyab, Bassein, Tavoy and Toungoo, the district rates in 1898 were lower than the quinquennial averages, and the district of Mergui was free from the disease. The highest district rates were registered in Akyab, 1·84 per 1,000, Bassein 1·69, and Kyaukpyu 1·32. Although thirteen of the 34 towns were free from the disease, the urban death-rate, 1·14 per 1,000, was nearly double the average of ·59 recorded in rural areas, deaths being fairly numerous in the populous towns of Akyab (cholera death-rate 7·46), Bassein (4·06), Thayetmyo (2·81), Moulmein (1·20), and Prome (1·07).

There were 177 deaths recorded in January, after which the number rose to a maximum of 637 in April, declining steadily until August, when it dropped to 102, after which it fell to 26 in September and remained low until the end of the year.

In the nine towns in Upper Burma in which vital statistics are registered, there were only four deaths ascribed to cholera, three in Myingyan and one in Pagan.

Summary of cholera registers.—The troops and the prison populations shared in the general immunity from cholera enjoyed by the people; and the following paragraphs, compiled from the cholera registers of outbreaks among troops and prisoners, show that even when cholera did appear among them it was, except in a few instances, limited to sporadic cases.

Cholera occurred among European troops in nine stations, and there were in all 30 cases and 21 deaths—case-mortality 70 per cent. In only one instance, at Umballa, where there were 20 seizures and 15 deaths, was the disease present in epidemic form. Of the 20 seizures at Umballa, nine occurred among native followers and four of them recovered, but 10 of the 11 Europeans attacked died. In other stations six of the attacks were single, and four of these terminated fatally.

Among Native troops, cholera occurred in six stations among 10 bodies of men, one of which suffered on two occasions. There were in all 57 cases, of which 44 ended in death, case-mortality 77·2 per cent.

Only eleven jails suffered, four in Bengal, two in Assam, two in Madras, and three in Burma. There were only 18 cases in all, and it is doubtful if the disease was true cholera in at least five instances. There were, however, nine deaths, equal to a case-mortality of 50 per cent.

There was no special prevalence of diarrhœa at the time of the occurrence of cholera, except in one instance, when a fatal case of doubtful cholera occurred in the Tezpur Jail.

The statement below shows, in all cases where the details are available, the number of buildings occupied by the communities attacked, and the proportion which furnished cases of the disease:—

Communities.	Number of buildings occupied by communities attacked.	Number of buildings which furnished cases.	Percentage of buildings which furnished cases.
European troops	131	15	11·45
Native troops	805	31	3·85
Prisoners	91	14	15·39

No special relation between particular meteorological conditions and the occurrence of cholera was established.

In one fatal outbreak among Europeans, the first attacked was of intemperate habits, and the day before his seizure, had visited a house in the bazar where there was a case of cholera. The occupant of the adjacent quarters visited the patient and was himself attacked on the following day. He recovered, and there was no other case.

Among Native troops there was no case in which cholera was imported in the sense used in this Report, but in many instances cholera was present in the neighbouring bazars or villages.

In two Bengal jails, prisoners were attacked on the third and fourth days respectively, after their admission from villages where cholera was prevalent. In neither instance did the disease spread.

The next statement shows, for the cases in respect of which details are available, the numbers treated, the numbers of attendants on these cases, and the numbers and percentages of the latter who were attacked :—

Communities.	Number of cholera cases treated.	Attendants.		Percentage of attendants attacked.
		Number.	Number of these attacked.	
European troops and followers ...	30	78	0	0
Native troops and followers	56	118	0	0
Prisoners	16	63	0	0

Among the sanitary defects noted, only the following seem likely to have been connected with the occurrence of cholera. The water supply at Umballa was liable to pollution. At Manipur drinking water was taken from a river on the bank of which there are villages in which there were cases of cholera.

Seven parties of European troops were moved in five stations. No attack occurred after movement, the effect of which on the general health was satisfactory.

Native troops were moved in three stations: at Rangoon the movement was entirely successful ; at Umballa one case occurred after the move ; at Manipur nine cases occurred after the move, although the medical officer states that the movement was quite successful. The account of the proceedings at Manipur is confusing, but it seems that the men and their families were moved in six parties into separate segregation camps, and from there into a general camp. In the segregation camps three cases occurred, in at least one of which the disease must have been contracted in Manipur. In the general camp five cases occurred, after which the camp was shifted to another site where one more case occurred.

The outbreak among European and Native troops and followers at Umballa is of special interest, as there was no case of cholera reported among the general population, indeed, except for two deaths that occurred in the district of Gurgaon in April, the Punjab was apparently free from the disease. In these circumstances it is unfortunate that the accounts of the outbreak at Umballa are of a fragmentary character, and it is difficult to piece the fragments. A suspicious case occurred on the 28th of April, when a syce died in the station followers' hospital with symptoms resembling those of cholera. Another suspicious case in a native is stated to have occurred on the 29th April, in which a fatal attack followed a self-administered purge taken to relieve the effects of a dietary indiscretion. The first case recorded as cholera was that of a European artilleryman who was under treatment in hospital. On the 29th of April he absented himself from the hospital, and remained out for several hours. He drank some beer and was exposed to the sun. Half an hour after his return to hospital he developed symptoms of cholera, and died collapsed on the 30th. The second case, also a European artilleryman, was admitted to hospital on the 1st May, but no connexion with the first case was traceable. On the 3rd May a private and a native follower were attacked ; on the 4th, two privates ; and on the 5th, two other privates and a follower ; and on the same day the disease appeared among the 16th Bengal Cavalry.

The Umballa cantonment water-supply is conveyed in pipes, but these pipes are very leaky, so that in the rainy seasons the yield of water from the pipe is greater than the supply to the pipe. "The vibrio of cholera was found in the well used by the Government Model Dairy," but no case occurred at the dairy, and neither the milk nor the butter from the dairy appear to have been used by the natives who suffered.

The medical officers who report upon the outbreak, ascribe it to the polluted water-supply ; but beyond the fact that the pipes were leaky, and the water consequently liable to pollution, there seems to be no evidence pointing to the water as the cause of the cholera.

SMALL-POX.

The mortality ratio of India from small-pox was in 1898 more than two and a half times less than 1897, and nearly one and a half times less than the ratio of the quinquennium 1893–97. The highest numbers of deaths occurred in the months of March, February, and April; and the lowest in October, November, and September. The reduction of deaths in the months of 1898 varied from great to considerable; and the total number of cases for the year was only 62,517, against 167,318. Only in Lower Burma and Ajmer-Merwara was the mortality higher than in 1897; and only in Lower Burma was it also higher than the mortality of the quinquennium as a whole.

The following shows the mortality from small-pox in the different provincial registration areas of India in 1898, month by month :—

Statement showing the deaths from Small-pox registered in the different Provinces by Months during the year 1898.

PROVINCES.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.	RATIO OF DEATHS PER 1,000 OF POPULATION.

* Excluding Zamindaris.

Bengal.—In Bengal the mortality ratio was reduced as compared with that of the previous year, though somewhat higher than that of the quinquennium. Statistics will be found in the above table. The greatest monthly numbers occurred in March and April, but they were lower than in the preceding year. Jalpaiguri rural district, as in 1897, had no small-pox mortality; Khulna had the lowest ratio; while Puri, which generally suffers much, returned the highest mortality. Regarding the severity of the disease in Puri, the Civil Surgeon, as quoted by the Sanitary Commissioner, says :—

"Small-pox was epidemic in a virulent form and claimed 5,508 victims, the largest number recorded of late years. . . . . The rapid increase from 1896 is remarkable. The disease seemed to spread up from Ganjam, and for the most part was worst in villages adjacent to the trunk road to Cuttack. It also took deep root in Bhubaneswar outpost, a hot-bed of obstruction to vaccination. It seems also to have spread in from the *mals* on the west side of the district, where I hear it has been fostered by the practice of inoculation.

Speaking at an outbreak of Cuttack in March, the Sanitary Commissioner declares that the practice of inoculation, which is still clandestinely carried on in many parts of Orissa, the unprotected condition of the neighbouring native States, and the opposition of the people to vaccination are the causes of these periodical outbreaks. Last year several inoculators were detected and criminally prosecuted, with the result that some were heavily fined and some sentenced to imprisonment. The highest town ratio was that of Colgong in the Bhagalpur district, and the town with the lowest ratio was Dacca. The year under review was the third year in which there had been no death from small-pox among the European seamen in the port of Calcutta. Among the native floating population also there were no deaths, against 8 in 1897.

Assam.—From the table given above it may be seen that small-pox mortality in Assam was lower than in 1897, but higher than the mortality of the preceding quinquennium as a whole. March, April, and February had the greatest monthly numbers;

and in the first and third the numbers were greater than in the preceding year. October, November, and December had the smallest numbers. The Sanitary Commissioner remarks that on the whole the disease has been very satisfactorily kept under by efficient vaccination. Of all the provinces except Madras, Assam had the highest rural mortality. The rural district with the highest ratio was Nowgong, and the lowest rural district ratio was that of Cachar. The highest and lowest town ratios were respectively those of Jowai, in the Khasi and Jaintia Hills, and of Sylhet. The outbreak at Jowai, which had spread from Gauhati, seems to have been stamped out by energetic vaccination operations.

North-Western Provinces and Oudh.—The statistics of small-pox in the North-Western Provinces and Oudh will be found on page 101. The mortality was about 37 times less than in the preceding year, and about 12 times less than the mortality of the quinquennium 1893–97 as a whole. The highest monthly numbers were those of April, May, and June; and the lowest, those of October, November, and September; and every month of the year had a very much lower number than the corresponding month of 1897. Of all the provinces this had the lowest rural ratio, and only in this province was the rural mortality lower than the urban. The highest rural district ratio was that of Gorakhpur, and the highest town ratio that of Mau, in the Azamgarh district.

Punjab.—Below both that of the preceding year and that of the quinquennium, was the small-pox mortality of 1898 in the Punjab. Statistical particulars are given in the table on page 101; every month of the year the reduction was great. The highest numbers were those of June, May, and July; and the lowest those of October, November, and December. The Sanitary Commissioner states that small-pox was much more prevalent from 1867 to 1879 than from 1879 to 1898; and points out that the latter period almost coincides with the age of the vaccination department as it is at present. The highest rural district ratio was that of Umballa; while Faridabad in the Delhi district had the highest town ratio, and Amritsar the lowest. The percentage of children's deaths in total small-pox mortality was, excluding Ajmer-Merwara, highest in the Punjab.

Central Provinces.—Small-pox mortality in the Central Provinces was much below that of the preceding year, as well as that of the quinquennium as a whole. The table on page 101 gives the necessary statistics. The maximum months were May, July, and June; and the minimum November, October, and February. Except in September and December, there were fewer small-pox deaths than in each corresponding month of 1897, the reduction being very great except in July, August, and November. The highest rural district ratio was that of Sambalpur, and the lowest that of Nimar; the highest town ratio that of Bargarh in the Sambalpur district, and the lowest that of Chanda.

Berar.—In Berar, as is shown in the table on page 101, the mortality from small-pox in 1898 was less than in 1897 and still more below the mortality of the quinquennium as a whole. The months of March, April, and February had most deaths, and the months of September, October, and November fewest. As compared with the corresponding months of 1897, February, March, July, August, September, and October had more, and all the others fewer, deaths, the reduction being greatest in December. The highest rural district ratio was that of Buldana, and the lowest that of Amraoti; the highest town ratio that of Deulgaon Raja in the Buldana district, and the lowest that of Amraoti. In Berar, out of all the provinces, the proportion of children in the small-pox mortality was lowest.

Madras.—Madras in 1898 had a small-pox mortality which was below that of the preceding year, though higher than that of the quinquennium, as may be seen in the table on page 101. The number of deaths was much increased in January and February, increased in March and April, considerably reduced in May–November, and much reduced in December. The Sanitary Commissioner observes within the last three years a steady improvement in the rates within municipal towns as compared with their surrounding rural areas; and thinks this possibly due to the order that the chairman shall give a complete account of the methods of disposal of all births that have been registered, and have arrived at an age to receive vaccination. The highest rural district ratio was that of Ganjam, which was also the highest district ratio in India, and the highest town ratio that of Berhampur in the Ganjam district. The Sanitary Commissioner says :—

It will be noticed that the frightful rate of 12·2 per 1,000 registered against Ganjam during 1897 has undergone a decline; but that in 1898 the mortality from this cause was still of a most serious nature. It will be remembered that the impetus given to the disease during 1897 was due to famine conditions leading to the crowding of the people upon works. What with the existence of extensive hill tracts

inhabited by a class of people who probably would much prefer inoculation to vaccination, and the impossibility of dealing satisfactorily with any sanitary subject in zamindari tracts, Ganjam presents a most unpromising field to the sanitarian. Indeed, so little has it been considered possible to deal with the district by ordinary methods, that for the last ten years, in the hill tracts, the entire responsibility for the administration of the Vaccination Department has been in the hands of the civil authorities.

The Sanitary Commissioner also points out that in judging of the magnitude of small-pox epidemics, it is well to hold in mind that under the present system of registration in rural areas, and to a less extent in municipal towns, deaths from measles are apt to be included under " small-pox."

The lowest rural district ratio was that of Malabar, and the lowest town ratio that of Calicut, in Malabar.

Coorg.—Small-pox mortality in Coorg was reduced, and only 22 deaths in all were registered. These facts may be gathered from the table on page 101. The reduction took place in February, June, August, November; the numbers in other months rising or remaining unaltered. There was no urban mortality. The highest rural district ratio was that of Kiggatnad, and the lowest that of Naujarajapatna.

Bombay.—The small-pox statistics of Bombay will be found in the table on page 101. The mortality was half that of the preceding year and of the quinquennium. March, April, and February saw the greatest numbers of deaths, and October, November, and August, the smallest numbers. As compared with the corresponding months of 1897, the numbers were much reduced in March-June, August, and December; reduced in July, January, February, October, and November; and increased in September, The Sanitary Commissioner says:—

These figures may be considered very satisfactory, and they testify to the exceedingly good vaccination work which now for some years past has been done in the presidency. After the experience of the famine year of 1877 and the following year, when 27,369 and 4,475 deaths from small-pox were recorded, it is very satisfactory to be able to state that, notwithstanding much better registration, the famine year of 1897 and the following year gave only 3,835 and 1,834 deaths from the same disease. This result is chiefly to be attributed to the progress vaccination work has made since the former period.

The fact, however, seems to be that small-pox infection was not wide-spread in 1898, so that the state of vaccination was not really put to the proof. The highest rural district ratio was that of Khandesh. Barsi in the Sholapur district had the highest town ratio, and Surat the lowest.

Lower Burma.—The ratio of mortality from small-pox in Lower Burma was almost two and a half times greater than the corresponding ratio of 1897, and nearly as much greater than the quinquennial ratio. The table on page 101 gives the figures. The maximum numbers of deaths were in April, March, and May, and the minimum in November, October, and September. From January to July the increase was great over the corresponding months of 1897, but in the remaining months the increase became less marked. Excepting Mysore, Lower Burma had the highest rural and the highest urban mortality of any province. The highest rural district ratio was that of Tharrawaddy, and the lowest that of Akyab. The highest town mortality, which was also the highest in India, was that of Zigon, in the Pegu district, and the lowest that of Akyab.

Plague.

The Bacillus.—In the report for 1897 the point was noticed, references being given, that the descriptions of the bacillus given respectively by Kitasato and by Yersin, did not agree the one with the other. And Kitasato has lately again called attention to the discrepancy in the following words:—

It has been quite generally assumed that the bacillus above described [the one discovered by the author] is identical with that of Yersin, but this assumption is incorrect . . . . Further bacteriological investigations of the plague are desirable, and it is necessary that the scientific world should come to some definite conclusion as to the etiological bacilli before orrhotherapy and preventive inoculation can be instituted on a truly rational basis.

Balfour Stewart gives a good account of the methods of plague bacteriological diagnosis in use in the Bombay laboratory. He mentions that bacilli which have been cultivated for some time do not behave in quite the same way in culture media as bacilli fresh from a case of plague. Klein found that in the buried bodies of guinea-pigs the bacilli retained life and infectivity for 17 days, but that in 21 days or over they could no longer be cultivated or successfully inoculated.

Rats.—Experimenting with guinea pigs, rats, rabbits, and monkeys, Batzaroff found that a minute quantity of plague culture placed, even without producing excoriation, upon the nasal mucous membrane produced plague pneumonia ; and that the plague virus, dried with some albuminous matter, produced, when similarly inoculated, the same effect. Infection could also be brought about, but with gradually diminishing ease, through the conjunctival, buccal, intestinal, rectal, and vaginal mucous membranes.

Being requested by the Municipal Commissioner of Bombay to express his opinion on the importance of rats in the diffusion of the plague, Professor Lustig offered the following remarks :—

1st. I have performed experiments on hundreds of rats of different races, and living in the most different conditions, and I have found that almost all are able to get plague.

2nd. Keeping in a cage several infected and non-infected rats, all die in a short time, and in their bodies plague microbes are always to be found.

3rd. Mixing a virulent plague culture with the food given to some rats, all these generally died from plague, and it is quite common to find the bacilli in their fæces.

4th. Generally in the infected rats the microbes enter the blood, and with great facility they pass into the urine. Thus this urine becomes a very infectant liquid.

5th. In 1897 I had occasion to examine at Poona some dead rats found in a granary, and in these I found plenty of microbes. I investigated also the corn of this granary, but I did not discover any plague microbes in it. Nevertheless, I know that two cooks who ate of this corn died from plague a few days after.

6th. I believe that the rats represent one of the most important means of diffusion of the disease, because they are able to carry everywhere virulent microbes.

The destruction of the rats is one of the most important measures to be taken against the plague. For this purpose poisons can be very useful, and specially would it be useful to provoke amongst the rats another epidemic with a microbe not virulent to man. For this purpose I believe that Loeffler's microbe would be the best, because it was used with satisfactory results in Thessaly some years ago. I got a culture of this microbe and tried it on white mice, and obtained a culture which was very virulent, but I had not success with the black rats. I know that the same was experienced by Dr. Galleotti, to whom I sent one of my cultures of Lœffler's microbe. Dr. Galleotti will receive in a short time from Prague another more virulent culture of the same microbe, and will repeat the experiments.

Manson also strongly believes that plague is a rat-borne disease, and that the most important *prophylactic* measure against plague is the destruction of rats ; and it has been asserted by another writer that one reason of Calcutta's relative immunity is the comparative scarcity of rats. The official plague reports of Calcutta, however, show no knowledge of any such scarcity : in fact rats are frequently mentioned. On the other hand, the following has been put forward as the conclusion to be derived from the evidence offered to the British Plague Commission :—

It seems, then, that while rats suffer from plague, and the death of unusually large numbers of these animals is an important sign of a place having become infected with this disease—all the more important as it may occur very early, before the few cases that have occurred have attracted the attention of the authorities—yet they do not play an important part in the actual spread of the disease, which may be very severe without any marked increased mortality among these rodents.

Meanwhile, it is safest that action should be inspired by the opinion that rats constitute a great danger.

Insects.—Nuttall, who had previously contributed much to knowledge of the subject, read before the British Medical Association an important paper on the subject of the part played by insects in the propagation of infective diseases. With regard to plague he says :—

An active part has recently been attributed by clinical writers to blood-sucking insects in plague. Bugs and fleas were supposed to be the active agents here. Experiments made by the writer on animals with plague, anthrax, mouse septicaemia, and chicken cholera, all gave negative results. In a large number of experiments made by allowing these insects to bite animals dying of the diseases named, and then immediately afterwards transferring them to healthy animals, not a single case of infection occurred. Though the dejecta of bugs contained virulent bacilli after twenty-four hours, they did not do so later. In fact, it was shown that both fleas and bugs digest various pathogenic bacteria which they have taken up with the blood of diseased animals. Simond (1898) goes so far in his elaborate theorising as to conclude that plague bacilli may acquire a heightened virulence in the bodies of such insects. He attributes a very important share to these insects in the propagation of plague, but gives no evidence to prove his assertions. The entirely negative results of my experiments should weigh more than gratuitous assumptions. That a bug or flea filled with the blood of a patient containing plague bacilli may serve as a passive carrier of the germs may be safely concluded from my experiments with these and other germs which were seen to remain alive and virulent in the bodies of these insects for twenty-four hours or longer when they were kept at low temperatures. If such an insect were crushed and the skin scratched by nails soiled with the blood it contained, infection might readily occur. In warm weather the insects are physiologically more alive, and consequently digest the micro-organisms more rapidly.

In another paper Nuttall, after mentioning that Simond had shown experimentally that rat-fleas, if placed upon them, will attack men and dogs, goes on to say that it appears to be unknown to Simond that the rat-flea belongs to a different family from the *pulex irritans*, and that it has yet to be proved that it will attack men under natural circumstances,* whatever may be the case in laboratory experiments. Mühling also from experiments with anthrax bacilli came to the conclusion that any danger there might be was not from the insect biting the man but from the man crushing the insect and scratching it into his skin.

Dust.—Neisser's experimental results support the opinion of Germano that there is no danger of the conveyance of plague by the dust floating in the air of rooms. The subject of the aërial conveyance of the disease is mentioned again in the abstract of the report of the German Plague Commission.

Infectiveness in convalescence.—It has been stated that plague bacilli have been found in the throat several days after the temperature had returned to normal.

Susceptible articles.—Kurth, of the Bremen Bacteriological Institute, after an examination of suspected jute, cotton, and hides, reported that he could find no evidence of the importation or of the likelihood of importation thereby of plague bacilli. It will be seen in a subsequent paragraph that the German Plague Commission formed the same opinion as regards hides.

Favouring conditions, mixed infections, natural course.—It has suggested itself to some minds that the outbreak of an epidemic is not due to the arrival of the bacillus, but to some change in the inhabitants or their environment; and it has even been hinted that in the intervals between epidemics the bacillus may lead a saprophytic existence, waiting for the return of conditions favourable to parasitism. If such be the case, the conditions must be such as affect men and rats simultaneously. An interesting and striking paper on the meteorological relations of plague, especially on its relation to vapour tension, is described as having been quite recently read by Mr. Baldwin Latham before the Royal Meteorological Society. The influence of vaccination against small-pox in strengthening resisting power against plague has also been discussed. Such vaccination has probably no effect. Pearse in a letter to the *Lancet* gives a list of the infective diseases from which Bombay patients have been found to be suffering along with plague. Some disease-viruses appeared to assist that of plague more than others did. Again, it has been stated that the mortality curves for the large cities of Poona, Bombay, and Calcutta for plague epidemics show great similarity; and that this points to the existence of a natural course and limit for a plague epidemic, a fact which must be taken into account in estimating the effect of measures adopted to arrest the progress of the outbreak.

Incubation, case-mortality, diagnosis.—Haffkine considers that the period of incubation is on the average five days, but may extend to 10. The case-mortality appears to vary between 50 and 90 per cent.; Müller puts it at 62, and Pearse at 75 or more. In practice a diagnosis has sometimes had to be made between influenzal pneumonia and plague pneumonia.

Inoculation.—The case for prophylactic inoculation has been clearly stated by Haffkine in a lecture before the Royal Society.

Mahamari.—With regard to Mahamari, Captain Leonard Rogers, I.M.S., records the following interesting remarks:—

> From inquiries that I have recently made in the Kumaon hills it appears that the term Mahamari is applied in these parts to any epidemic disease which is attended by a very high mortality, and under this name I have had a typical outbreak of cholera described to me by villagers. On the other hand, any infectious disease which is attended by a comparatively low mortality is called Sunjar, which term would probably include such diseases as measles and chicken-pox, &c., if they occur in these parts. From an examination of the records it appears to be certain that some of the outbreaks of so-called Mahamari are exactly similar to true plague, notably those of 1853–4, which spread down

* Sambon in J. T. M. of December 1899, page 119, agrees with Simond; but Galli-Valerio in C. B. XXVII., page 1, proves Simond to be probably wrong and certainly premature.

to the districts of Bijnor and Moradabad, and of 1876–7. It is, however, equally certain that this form of the disease may be absent from the hills for several years at a time, as for instance, between the years 1878 and 1881, when, although the whole of the villages of Kumaon and Garhwal were carefully inspected yearly and a special report made, no cases of the disease were found. Further, it seems likely from the descriptions that some of the outbreaks that have been returned as Mahamari have been outbreaks of typhus fever and not of plague, and that the latter are comparatively rare. Again, the outbreaks of the plague-like disease nearly always begin in the higher parts of the district, which border on Tibet, and it seems very probable that they originate in that country which, together with Yunnan, appears to be the home of the plague, from whence it spread to Canton and Hong Kong in 1893; and that it is more likely that the plague reached Bombay in that roundabout way than that it travelled direct from Garhwal to the western part of India.

German Plague Commission.—In the report for 1897 use was made of preliminary papers published by members of the German Plague Commission. Their official report is now published, and the following is a brief summary of some of the chief points :—

The question as to where the Bombay plague came from cannot be definitely settled; but the probability is that it came from the Mahamari region in Northern India, just as the plague of Canton in 1894 came from the endemic tract in Yunnan. Rats certainly played a part in the spread of the disease, but not mice. Whether the plague passes from rats to man by means of the excretions of the sick and dead animals or by means of insects, there can be no doubt of the danger of infected rats for man; but at the same time it is clear that under favourable circumstances plague can flourish without the help of rats. Though the evidence is not complete, it seems probable that insects do not play an important part in the conveyance of the disease. If they ever do, it is most likely to be in the overcrowded dwellings of the poor, where also the sputum of pneumonia cases is frequently received on the hands or clothes of the relatives of the sick. As the hospital staffs were hardly attacked, it seems pretty certain that mosquitoes at any rate were not concerned. The clinical forms are the Bubonic, the Pustular, and the Pulmonary. There is probably no *primary* plague septicæmia; and no cases of intestinal plague were met with. The presence of the bacillus in the blood is an *almost* certain precursor of death. The hæmorrhages so frequent in plague are not due to the bacilli directly but to the toxin, as is shown by the fact that fœtuses born of plague mothers, but themselves free from the bacillus, show them. In bubonic cases the bacillus is found in the buboes, and especially in the inflamed connective tissue surrounding the buboes; in pneumonic cases, in the lungs; in septicæmic cases in the blood, spleen, secondarily affected lymph glands, bone marrow, bile, often also in the urine, peritoneal fluid, juice of hypostatically congested lungs, fluid of plague meningitis, sometimes in the blood and milk of women in labour. The bacillus was found in the sputum of pneumonic cases, in the bronchitic sputum of septicæmic cases, and sometimes in the urine, but not in the skin-petechiæ, the saliva, the fæces, the sweat, nor in the milk* and lochia of plague-stricken women. Buboes that have undergone puriform liquefaction are sterile, but when true pus appears, it contains staphylococci and streptecocci, and occasionally plague bacilli if it has not become sterile. In the lungs the *bacillus pestis* is found alone or with the diplococcus, or the streptococcus, or the influenza bacillus, or the tubercle bacillus. These seem to prepare a favourable ground for the plague bacillus; and when a tuberculous man recovers from plague, his tubercular affection becomes rapidly worse. When a skin lesion is found, it is not always on the extremities, but sometimes on such out-of-the-way places as the navel, the buttocks, or the foreskin. From the habit children have of putting everything in their mouths, they are apt to have submaxillary buboes. The end of the third day is the normal end of the disease; all continuations are relapses of three days' duration each, or are due to complications and sequelae.

The *bacillus pestis* possesses a capsule. It is non-motile, and has no flagella. It cannot be stained by Gram's method. It does not form spores. Well-marked involution forms appear in cultivations, especially in agar containing salt, and in corpses. It flourishes well between 30° and 37° C., not showing any evident optimum, but it seems as if a temperature somewhat below 20° were better for it than body temperature. At temperatures below 20° its growth is proportionately delayed. But at all temperatures its growth is markedly slow. It is strictly aërobic, and grows best in slightly alkaline media, requiring, however, a pretty high degree of concentration in its food. Pure cultures protected from drying and from light retain their vitality for months. The bacilli cannot stand quick and energetic drying. Apparently quick drying at a high temperature is more speedily fatal to them than slow drying at a low temperature. It is, therefore, not likely that in hot countries they can be carried in dust. Exposed to the sun, a thin layer dies more quickly than a thick one; but keeping the layer cool with water preserves its vitality. A layer on wool remains longer pathogenic than one on silk. Moist heat at 55°, 60°, or 70° C. killed the bacilli in 10 minutes, at 80° in 5 minutes, and at 100° at once. In the laboratory the best disinfectants were found to be steam, carbolic acid, lysol, corrosive sublimate, chloride of lime, milk of lime. In pneumonic sputum preserved for 16 days there were no longer any virulent bacilli, though there had been on the 10th day. In ordinary pipe water the bacilli were no longer virulent after five days, and in sterile water after ten days. In sterilized fæces and urine they did not live longer than five days. All the experiments show that the *bacillus pestis* possesses little resisting power, and it does not appear likely that it produces a resting form.

Rodents possess less resisting power against the plague bacillus than other animals, and the rat the least of all. But the grey monkey (*semnopithecus entellus*) is nearly as sensitive. On the other hand, horses, cattle, sheep, and goats fall sick when inoculated with large doses, but practically always recover; so that they are not likely to acquire the disease naturally, and their hides are not likely to

---

* There seems some discrepancy between the statements about the presence or absence of the bacillus in the milk of women, on pages 79 and 273 of the German Report.

be dangerous. Bodies of cats were sometimes brought in, but the animals seemed to have really died of starvation ;* and cats soon recovered when inoculated. Dogs are not susceptible, or very little ; pigs are almost completely insusceptible ; birds are insusceptible.

Plague is, like anthrax, rather infective than toxic, but the toxin counts for something in human plague. Experiments on animals show that the toxic action is not very great, not nearly so great as in enteric fever and cholera, not to mention diphtheria. Man seems to be comparatively tolerant of the poison ; but a man who has recovered from plague reacts more strongly than a healthy man to an injection of dead bacilli. The agglutinating action of plague serum is not of absolute value : a negative result cannot be used against the diagnosis "plague," but a positive reaction is a very valuable criterion of plague having been passed through. Again, plague serum is an excellent means for the differential diagnosis of true plague bacilli from those resembling them. As with cholera and enteric fever, the agglutinating action of the serum is in no way parallel to its protective and immunizing effects.

Experiments on animals gave hope for the success of preventive inoculation, and the results in man, so far as they went, were also favourable, but only experience can finally decide. With regard to the therapeutic use of serum, the only certain conclusion so far is that it does not produce directly or indirectly any visible harmful effects.

In a lecture before the German Public Health Society, R. Pfeiffer, of the German Plague Commission, gave a short and clear account of the results of the labours of the Commission.

Müller, of the Austrian Plague Commission, did not find any evidence of the agency of insects in the conveyance of infection. The bacteriological part of the Austrian report does not seem to have been published yet, only the clinical part being available.

The Plague Commission appointed by the Right Honourable the Secretary of State arrived in India in November and left in March, 1899. The report has not yet been published.

Other Reports.—Yersin, who shares Simond's views as to the large part taken by insects in the propagation of the disease, has published a report on the plague at Nhatrang in Annam. Total evacuation of the infected village, transfer of the inhabitants to a temporary village on a new site, destruction of the infected houses and those immediately surrounding them by fire, were the principal effective measures. A report by Dr. Gomes da Silva regarding the plague at Macao and Lappa in 1897 has also appeared. Finally, Dr. Favre has written on an as yet not completely investigated "plague-like" disease which attracted attention in the years 1888—94 in a remote corner of Siberia, which is said to be spread by a species of rodent, a marmot, and which the people are said to combat by evacuation, isolation, and fire.

Conclusions.—No new fact of importance regarding plague has been discovered since paragraph 176 of the report for 1897 was written (page 119 of Parliamentary Report, C. 9549). While rats have continued to maintain their importance, no fresh evidence has been obtained in favour of the alleged active rôle of insects in the propagation of the disease. The point raised by Kitasato, as quoted on page 103, is one that should be settled.

Plague in 1898.—The conclusions as to the method of progress of the disease and as to the measures adopted by the authorities must be much the same as those given in paragraph 187 (page 126 of Parliamentary Report, C. 9549), and paragraph 206 (page 135 of Parliamentary Report, C. 9549) of the report for 1897. The only change in measures, besides the improvement due to experience, was in the direction of mildening and popularizing them : not because the rules, which were scientifically stringent, were in themselves undesirable, but because it was found impracticable to carry them out in all their fulness, at least in the large towns. Endeavours were made, in various ways, to reconcile the people to the measures taken for their benefit, and to enlist the help of respectable and intelligent members of the native community. Where these were successful, the result, on the whole, was that, while certain desirable benefits had to be sacrificed, the detection of cases, the very basis of all possible measures, was facilitated.

Plague appeared indigenously for the first time in Bengal, Rajputana, the Central Provinces, Mysore, and Madras, but did not recur in Central India or Garhwal. The following tables show the statistics of the Indian plague of 1898, so far as they have been

* But see Lorans in B. M. J., 2nd December, 1899, page 1588.

received in this office ; but both the figures and the list of localities are certainly very incomplete :—

Statement showing the deaths from Plague in the different Provinces by Months during the year 1898.

For Aundh and Sachin the figures of 1898 cannot be given separately. From September, 1896, to 30th December, 1898, they had, respectively, 1,216 and 275 deaths.
* These had no plague in 1897.

Part of the increase was no doubt due to the greater success attained in the detection and registration of cases: but the tables show that the disease both extended its boundaries and attacked more men in 1898.

On the 10th January, 1898, the Bombay Government issued instructions regarding plague administration for the general guidance of district and other officers. A copy of these instructions is printed as an appendix to this section.* In their resolution of the 3rd February, 1898, the Government of India expressed general approval of these rules, at the same time laying down their views on certain points of plague administration. These points were :—general organization for the detection of cases ; the unpopularity, and consequent ineffectiveness of corpse-inspection ; the division of towns into wards of manageable size, each under a European officer of influence aided by respectable natives of standing, and by female medical attendants for the inspection of women ; the necessity

* Not reprinted.

that segregation should be carried out in hospitals or other suitable places specially appointed for the purpose ; the good to be obtained by carefully explaining to the people the reasons for the measures, by getting the co-operation of leading native men, by paying due regard to the feelings and habits of the people, by encouraging the people to make segregation arrangements for themselves, and by refraining from separating the members of families ; the need for encouraging inoculation, while keeping it strictly voluntary ; the importance of making efficient arrangements to prevent people from returning to occupy evacuated houses before the time specified, and of securing that all articles likely to convey infection are without exception removed from infected houses and immediately destroyed or disinfected ; the reasons why the Government disapproves of sea or land quarantine ; the reason why the Government disapproves, as a rule, of the use of cordons ; in completion of the terms of the Venice Convention, approval of railway medical inspection being conducted so as to provide for the detention in the observation camp not only of persons in whom symptoms of plague or suspicious symptoms are discovered, but of all persons from the infected area who appear to be suspicious by reason of their appearance, the dirty condition of their clothes, the fact that they are travelling in gangs, or belong to classes which are likely to disseminate the disease or to be untraceable on arrival at their destination or which cannot be depended upon to give information should plague occur among them after arrival at their destination, all other persons being allowed to proceed to their destination after inspection, and the rules not being allowed to exempt any class of persons as such or any railway class ; finally, arrangements for checking the danger caused by pilgrimages.

Plague in the Bombay Presidency.—At the end of 1896 there had been a total of 2,909 attacks and 2,086 deaths from plague ; 61,093 attacks and 46,944 deaths were recorded during 1897 ; while 1898 saw 110,369 attacks and 86,191 deaths. The number of towns and villages affected was 1,188 against 912 in 1897. The deaths from plague in 1897 had been nearly exactly the same in number as the cholera deaths during the worst cholera year in the previous nineteen years. The heaviest mortality from cholera during the last twenty years occurred in the year 1897, but the plague deaths in 1898 exceeded this by 29,082. The parts most affected were the collectorates of Dharwar, City of Bombay, and Belgam, and the rates of plague deaths in them were 26·4, 22·4, and 16·1, respectively. Satara came next with a rate of 5·6, and then Kurrachee, Thana, Surat, Nasik, and Sholapur (2·08), the rates of the remaining affected collectorates being much lower. The only parts of Sind which returned indigenous cases were the towns of Kurrachee and Kotri, the former suffering severely. Except for a few imported cases, the collectorate of Ahmedabad was entirely free. With the foregoing exceptions, all the collectorates in the Presidency were more or less affected.

Recognizing that the plague had come to stay, and that it was impracticable over a large area and a prolonged period of time to close the ordinary channels of daily business and intercourse without very sorely trying the patience of the public and jeopardizing general prosperity, the Government of Bombay by their Resolution of the 17th October, 1898, made certain changes in the method of dealing under the Epidemic Diseases Act with travellers by railway. Railway detention camps and passes were discontinued, and replaced by a very strict medical examination, accompanied by disinfection of clothing, where necessary, at convenient railway centres and at places of arrival. Persons coming from infected localities were ordered to be subject to surveillance for ten days after arrival. It was ordered that at each examining station the examination should be conducted in the same way as for passengers departing by sea from Bombay. The detailed orders as to examination, disinfection, and surveillance were so worded as to endeavour to secure the maximum preventive efficiency with the minimum of inconvenience to travellers. Persons travelling with certificates of inoculation, provided the date of such inoculation was certified to be within the last six months but not within the ten days immediately preceding, and provided the identity of the holders was not open to doubt, were ordinarily to be allowed to pass with the examination prescribed for first and second class passengers, except that they would probably be required to detrain. Discretion was left to local authorities to issue such orders as might be necessary, consistent with the general instructions and declared policy of government, as to special regulations for travellers who could not be depended upon to give a trustworthy account of their residence and movements or were suspicious whether by reason of their appearance or symptoms or the dirty condition of their clothes or effects. But in the orders regarding the surveillance of new arrivals it was emphatically laid down that under no circumstances would any respectable healthy person who could give a reference either in the place he came from or in the place at which he had arrived be detained.

Plague in Bombay City.—Full details regarding the disease and the measures adopted against it are given in the report of the Municipal Commissioner.

The second part of his Report is devoted to the subject of hospitals, public and private, to the consideration by the medical officers of plague as a disease, and to the results of the use of various sera.

It was, in fact, found impossible in the city of Bombay to detect all cases of plague either before or after the outbreak had attained epidemic proportions ; and the number of plague deaths escaping discovery increased with the severity of the epidemic to such an extent that when plague was at its worst it was not certain that much more than half the plague deaths had been correctly ascertained. Also, when plague cases were discovered, their discovery was in many cases too late to prevent the escape of those who ought to have been segregrated or placed under surveillance. It was found, too, that specially stringent measures for the discovery of cases led to organized and extensive concealment. The general conclusion arrived at by the local government was that the efficiency of the measures approved by the Government of India in their Resolution of the 3rd of February, 1898, depends mainly on the exhaustive discovery of plague cases. Where cases remain undiscovered, measures, however well devised, must fail ; for undiscovered sources of infection, both personal and local, remain. The system which will result in leaving fewest cases undiscovered will be the most effective ; and experience in the city of Bombay has indicated as best that particular system which causes the least amount of popular resistance and discontent, while securing a treatment of infected persons and places such as to prevent any serious danger from them after they have been discovered.

Plague in the Port of Bombay.—During the year 71,498 vessels of all sorts with 1,207,571 crew and passengers were examined. The number includes every person who left Bombay by sea during the year, as well as those who arrived from the ports of Western India between Kurrachee and Bhatkal, inclusive, between the dates of 1st January and 20th April. After the latter date, and up to the end of the year, arrivals from infected ports only were subjected to a medical examination. The total number of plague cases detected during the year was 118. On vessels and native craft in the harbour 17 cases were found. Besides these, 96 cases were prevented from sailing on vessels leaving the port, and five were discovered on vessels coming from infected ports close to Bombay. A special sanitary police force was found necessary to assist the port health staff in carrying out the provisions of the Venice Convention. Government, therefore, sanctioned 12 European and 50 native police for such work, and placed them under the orders of the Port Health Officer. Owing to the marked recrudescence of the plague in January, an exodus set in, and 30,878 more people left Bombay by sea than arrived during that month. They where chiefly millhands and labourers who had their homes along the coast in close proximity to Bombay. In order to prevent the spread of plague to the coast ports, Government directed that in addition to the inspection before leaving Bombay, the people were to be inspected a second time at the port of arrival. Native craft were prohibited from taking passengers, so that the inspections at the coast ports could be carried out at the places where the steamers called. Afterwards, owing to the diminution of plague along the coast ports near Bombay, inward sea inspections from such places were suspended on the 20th April, and only vessels coming from infected ports were examined. When the third marked epidemic of plague in Bombay commenced towards the end of the year, arrangements were made with the Peninsular and Oriental Company for the disinfection of all clothing and bedding of the native crews prior to sailing. This disinfection has now been extended to the clothing and bedding of all native crews bound to any port out of India, aud is said to be working satisfactorily. Since the 1st September the inspection of the crews and passengers of outward-bound vessels which sailed to ports other than Indian ports has been made on shore prior to their embarkation, as directed by the Venice Sanitary Convention. The ship's company was again inspected on board before the issue of a Bill of Health immediately before departure from Bombay. The Bill of Health form was also revised accordingly. Experience has shown that a slight rise of body temperature proceeds the more definite signs of plague ; and, notwithstanding the difficulties due to the prejudices and carelessness of the people, the clinical thermometer was diligently used. In some cases it was found that passengers suffering from a rise of temperature had tried to reduce it immediately before examination by wetting their bodies with water, sucking ice, or taking doses of phenacetine. The newspapers reported cases of plague from Bombay at foreign ports from time to time ;

but subsequent inquiry in almost all cases proved they were not cases of plague, as in instances which occurred at Suez and Colombo. As far as is known at Bombay, also, plague broke out at Tamatave, Madagascar, in November and December, 1898, that is fifteen months after the last steamer left Bombay for Madagascar.

Plague in Bengal.—The plague deaths shown opposite Bengal in the table on page 108 belong, with the exception of 16, to the city of Calcutta. The alleged occurrence of plague in Calcutta in 1896 was discussed in the report for that year. On the 15th of April, 1898, the Health Officer was informed of the finding of dead rats, and on the 17th he saw the first human case brought to his notice. Though this was not really the first case that had occurred, he believed it to be a very early one, because noticeable rat mortality was of only quite recent occurrence. The diagnosis in this case was bacteriologically confirmed by Mr. Haffkine. One of the domes who assisted at the *post-mortem* examination, and who had then scratched himself on a point of bone, became ill with fever two days after, and died in fourteen days from what was believed to be plague. Four other domes contracted the disease in a similar manner. As usual, at the beginning of the outbreak there was a number of cases which were difficult to diagnose; and there were at first, and even afterwards, many persons who disbelieved in the reality of the visitation. Another ground of disbelief was the slowness of its spread, the absence of manifest epidemicity, and the low general mortality of the city; but the high case-mortality, the clinical symptoms, the pathological appearances, and above all the repeated positive results obtained by competent bacteriologists, stamped the disease as true plague. Most of the cases occurred in the middle of the town; the north, south, and east being practically free. Very little evidence could be obtained as to the manner in which the infection was carried from place to place or from person to person, partly on account of the difficulty of getting an accurate history. In the case of a European who lived in airy rooms on the roof of a lofty building, information was given that his pet dog brought a dead rat, and deposited it in his bed. At one time dead rats began to be noticed in considerable numbers in the General Market, in the neighbourhood of which human cases had been occurring, and were found on investigation to have died of plague. The entire market was very thoroughly disinfected, coolies being put on and working in shifts night and day. In this area human cases were discovered before rodent, but the Health Officer thinks from the way the disease appeared amongst different classes all round this quarter and the suddenness of the onset, that it is much more probable that infection of rats came first, though it was not discovered till after several cases had occurred. The network of sewers and the fact that the rats of one area can infect the rats of another area, even if they do not travel long distances themselves, render infection easy. Whether the disease is conveyed from infected rats to human beings by the germs incubating in the floors and ground, or through the agency of vermin on the rats, the Health Officer has no evidence to offer. In some houses the death of rats was not followed by plague, although plague cases always took place in the vicinity. The aims of the measures adopted were, as usual, detection of cases, segregation of sick and "contacts," evacuation of infected houses and localities, disinfection of infected houses and localities, and the improvement of general sanitation. But, to allay the alarm of the people, who were already beginning to leave Calcutta in large numbers, the following announcements were made :—

> Quarantine will not be enforced by Government against Calcutta.
>
> No segregation will be enforced if the entire household has been inoculated.
>
> No one will be declared plague-stricken without being seen by a competent medical officer, male or female, deputed by the municipality.
>
> No one will be separated from his or her family. If necessary, all will go together to a camp, where the *purdah* will be respected.
>
> Compensation will be paid on the spot, if any property is destroyed in being disinfected.
>
> Encouragement will be given to the public to provide private family hospitals for the treatment of their relatives in their private houses, where proper accommodation is obtainable.
>
> No person will be removed except on the order of a medical officer. The police are not authorised to examine or remove any one.

The period following the announcement of plague was characterised by organization on the part of the authorities; by panics, strikes, and disturbances amongst the lower classes of the people. In the districts and wards, committees were formed, whose duties were to make house-to-house inquiries as to the health of the people and report suspicious cases;

to establish ward and caste hospitals, and to report any serious sanitary defects. These committees mostly worked well, but they failed to gain the confidence of the people, who concealed cases from them almost as much as they did from the executive. As they had no power of entry, they could only accept what they were told. So the net result of their arduous and disinterested labours was somewhat disappointing, so far as the detection of cases was concerned. In fact, the greatest difficulty in dealing with the plague was the distrust and suspicion with which all plague officers were treated. Some inoculation was done, but its progress was stayed by the angry excitement caused by the circulation of wild stories prompted by malice or ignorance. Ultimately, owing to the small amount of plague, the absence of scare, and the removal of the office from the Health Office to the Town Hall, the number of people seeking inoculation decreased rapidly, until only those who desired to travel by rail, under the Government Notification of 30th October, 1898, without the inconvenience of detention at the inspection camps, came for inoculation. On the 10th of October, Calcutta was declared free from plague under the terms of the Venice Convention. The Special Health Officer remarked that the course of the plague in Calcutta was anomalous, and that, although isolation, as well as vacation of affected spots, had been thoroughly carried out, it was too much to hope that its diminution was due to those measures only, in view of their reported failure in preventing the spread of plague elsewhere. He was convinced that sporadic cases were still occurring, and that the up-keep of the organization for dealing with the disease was justified. Though such cases were few, inquiry was rendered difficult by fictitious addresses being given at the burning ghât, by lying statements being made by the occupiers of houses where deaths had occurred, and by false statements being furnished by the *kavirajes* and practitioners attending the cases. The lapse of time, unfortunately, demonstrated the correctness of the Special Health Officer's opinion, as ten more deaths occurred before the end of the year, in four of which bacteriological examination was used to support the diagnosis. At this time the cases were occurring chiefly amongst the Marwari community. There was great dread of Calcutta being again declared infected, and cases were systematically concealed. It was not, however, till February, 1899, that the increasing number of cases caused Government to re-impose the rules.

Besides the deaths in Calcutta, five occurred at Chausa (Railway Inspection Station), one in March, one in June, two in July, and one in August; and eleven in villages in the Backergunge district. Seven of the deaths in Calcutta, two of those at Chausa, and all the eleven in Backergunge were in direct connection with cases that had occurred in a house in Calcutta. Two of the remaining Chausa deaths were also due to Calcutta, and the fifth was that of a man who had come from Jullundur. The affected locality in Backergunge consisted of the two adjacent villages of Siddhakati and Abhoynil, about three miles south of Nalchiti, a small trading town with a municipality and a steamer station. The affected villages consisted of a number of scattered homesteads, each of which is well separated from its neighbour. The inhabitants, with few exceptions, showed a very reasonable spirit, and helped in the evacuation and burning down of the infected huts, and in the segregation of the sick and their families. For the houses burnt full compensation was paid.

The four plague observation camps at Chausa, Chakradharpore, Mairwa, and Khurda Road, which were established along the western frontier of Bengal to guard against the importation of plague into it by railway passengers from Bombay and other affected places, were in full working order throughout 1898, the second and third having been opened on 22nd February and 19th January respectively. The examinatian of passengers was conducted in the same way as in 1897. At the Chausa camp, which was the most important of all, the total number of persons inspected and detained amounted to 636,819 and 24,776 respectively. Among those detained at Chausa there were only 18 deaths, five of which, as already stated, were from plague (four bubonic and one pneumonic). There were no plague deaths in the other camps.

No Jeddah pilgrim vessel left Calcutta, nor did any arrive, during the year. The embarkation of pilgrims took place from Chittagong. Two hundred and twenty-seven vessels arrived during the year from the plague-infected ports of Bombay, Kurrachee, Hong Kong, and the Hedjaz. No case of plague was found on any of these vessels; but one of them, from Hong Kong, had had a case of plague removed from her at Penang. One case was found in connection with the shipping in the person of a customs officer; but after his death the attempt to cultivate the plague bacillus from his organs failed. The vessel was disinfected.

Plague in the Punjab.—For the Punjab the plague statistics are given in the table on page 108, as well as in the following :—

Months.	Jullundur.		Hoshiarpur.		Total.	
	Cases.	Deaths.	Cases.	Deaths.	Cases.	Deaths.
January	19	11	17	12	36	23
February	211	191	72	31	283	222

December	11	7	—	—	11	7
Total	2,458	1,633	677	386	3,135	2,019

During January no fresh infected villages were discovered, but in February 15 were found. In March, in which month 27 more villages became infected, a system of rewards for early information regarding newly attacked villages came fully into force, and is said to have probably had better results than any other system. The heavy punishment meted out to some lumbardars for concealing the existence of the disease in their villages had also a very salutary effect. During April 34 new villages were attacked, but in May only eight, and after July no new village was attacked until the fourth quarter of the year. During June occurred two or three isolated cases of what seemed to be a mild form of plague. In no case was the patient very ill, nor did the infection spread to other members of the family. This, it is considered, probably indicates that the disease had taken on the mild form noticed by others at the beginning or at the end of epidemics. Such cases require special information, as, if not promptly recognised and treated, they may be the means of keeping plague extant in a district from one cold weather to the next. In paragraphs 182, 196, 197, and pages 193 and 205 of the report for 1897 are mentioned the chief conclusions formed as to the mode of spread of plague in the Punjab, and specimens of the measures adopted. A cordon was drawn round the affected village ; a nominal roll of those within the cordon was taken ; the village was totally evacuated ; the inhabitants were removed to "healthy" and segregation camps, the latter with its inmates and their belongings being subjected to disinfection ; the village was thoroughly disinfected ; and the inhabitants were not allowed to return to their disinfected village till three weeks in summer, or one month in winter, had elapsed since the occurrence of a case in camp. It was noticed that plague re-introduced into a disinfected village showed little or no tendency to spread, and might usually be checked by the evacuation of one or two houses. With regard to the efficacy of evacuation the Deputy Sanitary Commissioner, Captain James, I. M. S., says :—

> It is therefore fairly well established that in evacuation we have a method of quickly and certainly stamping out plague. In not a single village in the areas under consideration can it be said to have failed. It was successful in every season of the year, though it took longer in the winter than in the summer. It was equally successful in large villages of from 3,000 to 6,000 people as in little hamlets.

The disease usually declared itself within five days after exposure to infection. With regard to Haffkine's system of preventive inoculation the summing-up given is as follows :—

> It is only when the prophylactic has been tried in a large number of cases all over the country and under varying conditions that a definite decision as to its efficacy in protecting against plague will be arrived at. It will never be the sole remedy against the progress of the malady, but it may possibly become one of the chief measures. Small-pox is not nearly so infectious as this disease, and yet we have a more perfect protective serum to combat it, namely, vaccine lymph. This remedy has now been tried for a hundred years, and tried on a very extensive scale. It has considerably diminished the amount of small-pox in existence, but it has not banished it. In the same way, it is impossible to believe that any form of protective inoculation can ever be effective if used as the only means of preventing infection. It is extremely difficult to inoculate large communities, and a few will always

escape, and those few have the power of keeping the disease in existence, ready to break out again when favourable conditions arise ; if, on the other hand, we look upon the inoculation as one, but only one, of the excellent sanitary measures which science has given us to combat this malady, then there is every hope of its becoming a powerful weapon in our hands.

Plague in the North-Western Provinces and Oudh.—The plague statistics of the North-Western Provinces and Oudh for 1898 are shown in the table on page 108. There were 191 seizures with 148 deaths against 97 and 72 in 1897. The disease remained confined to the Saharanpur district. The first case occurred in Jawalapur on the 9th January. The actual mode of introduction is unknown ; but as this town is only a short distance from some of the infected areas, the attack was confidently anticipated by the Sanitary Commissioner. The disease rapidly spread, and, as in Kankhal, cannot be said to have been arrested until the entire town had been evacuated. Cases continued to occur in the camps until the 28th May. The town having been completely and thoroughly disinfected, the people began to return to their houses about the middle of April. By this time the active measures taken as regards the infected villages in the neighbourhood had also been successful, and it may be said that the end of May saw this alarming outbreak completely stamped out. The provinces have since then been entirely free from the disease.

Excluding those in Jawalapur and villages in its vicinity, no cases are known to have occurred in the North-Western Provinces and Oudh during 1898, though alarms were frequent. Nevertheless, the Sanitary Commissioner retains the opinion expressed in his report for 1897, that such cases must have occurred. The memorandum issued by the local government as to the measures to be adopted in small centres of population was, he believes, of great value, because it is probable that when an isolated plague case was imported into a rural centre the people themselves took the necessary steps of isolating the patient, etc., without making any report to the authorities.

The measures adopted for keeping plague out of the provinces, and for fighting it after it had gained an entrance, were on the same lines as those described in the report for 1897.

Plague in the Central Provinces.—From September 1896, when the existence of plague was first recognized in Bombay, up to November 1898, the protective measures which were at first adopted and which still continue to be in force in the Central Provinces, and which consist chiefly of inspection of railway travellers, disinfection of clothing, detention of suspected persons, and police supervision of new arrivals, were successful in preventing the disease from obtaining a foothold in the province. During this period 22 cases of plague were detected at the various inspecting stations, 16 of them in 1897. At the end of October 1898 the disease was communicated by a traveller to a person residing permanently in Khandwa. In the first week of November the disease appeared in an epidemic form in the town of Hinganghat, extending afterwards to Wardha, and several villages in the Wardha district, also to the towns of Nagpur and Bhandara before the close of the year. At Khandwa the action taken was prompt and vigorous, and the disease spread no further. The precise origin of the outbreak in Hinganghat will never be known. The infection was doubtless brought in some way from Bombay, but whether by human agency or through the medium of goods brought by railway has not been discovered. It is, however, certain that the disease must have been in existence in the town for many days before it was actually recognized. Had this not been so, it doubtless might have been stamped out at once, as at Khandwa. The measures taken to combat these outbreaks were much the same in all cases. Briefly, they consisted of—

(1) Evacuation of the infected block in the first instance and eventually of the *mohalla*, including—

(*a*) Isolation of the sick ;

(*b*) Segregation of contracts ;

(*c*) Formation of observation camps for the other inhabitants ;

(2) Preliminary disinfection of infected houses ;

(3) Unroofing and thorough exposure to sunlight ;

(4) Final disinfection and cleansing prior to re-occupation ;

(5) Disinfection of grain ;

(6) Prophylactic inoculation.

"The total number of persons inoculated amounted to only 653. Its value is now, however, becoming generally recognized, and it is most satisfactory to find that the people

everywhere showed the greatest readiness to take advantage of it." From the experience hitherto gained the Administration concludes that careful railway inspection is a most valuable and indispensable protection against the importation of plague; that early intelligence of a first case of plague and prompt isolation of the sick person and those who have been in contact with him is of supreme importance, and decisively effectual in preventing the spread of infection; that, after isolation, immediate evacuation is the first and most effectual measure, but that to be effectual it must be complete, all communication with the evacuated block of houses being cut off; that when the infection is established, a house-to-house visitation is the only effectual means of bringing cases to light; that it is dangerous to allow people to establish scattered camps in such numbers or positions that control is difficult or impossible; that if disinfection has been thoroughly done, re-occupation may safely be allowed after the expiry of a period of six weeks from the occurrence of the last case.

The Sanitary Commissioner states that in no instance was there any fact disclosed in support of a theory of dissemination by the agency of rats or other vermin, except in so far that the death of rats at Hinganghat and Wardha coincided with the appearance of the disease among human beings, and that in the Khandwa outbreak and in another occurrence in the Deputy Commissioner's compound at Wardha, the mortality among rats occurred after the appearance of the disease among human beings.

Plague in Mysore.—The situation of Bangalore as the point of convergence of four lines of railway always rendered it liable to the importation of Plague. Two of these lines, namely, the main Southern Maratha Line, which runs directly from Poona, *viâ* Dharwar, Hubli, and Belgam, to Bangalore, and the branch to Guntakal, which joins the main line running *viâ* Sholapur and Poona, connected Bangalore with several centres of the disease in the Bombay presidency. Anxiety was therefore early felt at the possibility of infection by this means, and immediately on the passing of the Epidemic Diseases Act (III. of 1897), steps were taken to establish a system of railway inspection. Although the first case of plague in Bangalore occurred in the civil and military station, it could have had no connexion with the outbreak that immediately followed it in the city. This case was the servant of a railway official who arrived with his master from Hubli on the 11th August, and was found to be ill on the 12th. On the 13th cases were found to have occurred in railway cooly families living near the railway sheds of the Southern Mahratta Railway. These coolies worked at the railway transhipping goods-sheds; the disease was confined for some time to these people and their friends; and the entrance to the goods-shed is extremely close to the first infected houses. It seems, therefore, that the importation of the plague was due in some way to the Southern Mahratta Railway; but whether the infection was brought by railway servants from Hubli, or by clothes belonging to infected persons, or by goods or by rats, it is impossible to say. At the same time, the fact that it was the coolies in the goods-shed, and not the other railway servants, that were first affected, rather points to the latter two sources. The diagnosis of the first cases was verified by bacteriological examination. The disease at first spread very slowly. Its progress by months and districts is shown in the following table, as well as in that given on page 108.

No.	Districts.	August.		September		October.		November.		December.		Remarks.
		Cases.	Deaths.	Cases.	Deaths.	Cases.	Deaths.	Cases.	Deaths.	Cases.	Deaths.

An endeavour was made to keep in view for ten days all who arrived in Bangalore, and, by a system of passes, to prevent men likely to carry infection from leaving. Unfortunately from ignorance and timidity, the inhabitants gave no help or were, for the most part

passively, obstructive: so that for long the detection of cases, the segregation of the sick and those in contact with them, and the evacuation of infected localities were only partially attained. As these are measures which can be successful only when complete, it was difficult to get the disease in hand. The staff of the plague hospital, too, deserted, and a new staff had to be imported. Such was the fear of the inhabitants that they not only deserted their dead in their houses, but cast them forth to the number of over 200 into the roads, tanks, and wells. In fact, it was found impossible to "fight the people and deal effectively with the plague at the same time" and the rigour of the original regulations and measures had to be somewhat relaxed, in doing which, however, great care had to be taken that things did not slide to the opposite extreme. In some few cases at Mysore, the attitude of the Mahommedan inhabitants was threatening, and the Durbar authorities had considerable difficulty in dealing with them. At Bangalore trusting to death certificates was found useless, as was the refusal of burial without a certificate. The only measure of the kind at all successful was the making it penal to remove a body from a house without a certificate. Strange to say, the population, so adverse to the other measures meant for their good, took kindly to inoculation. Accurate statistics are not available; but the numbers reported are 30,758 first inoculations and 968 second inoculations by civil officers, and 11,815 first inoculations and 5,639 second inoculations by military officers. Of the civil inoculates, 379 were reported to have been attacked and 263 to have died.

Rewards were offered for the destructiou of rats; and in a report dated November it is noted that dead rats teeming with plague bacilli had been found in every quarter of the city and station of Bangalore, so that the entire locality appeared to be infected,

Plague in the City of Madras.—Thirteen imported and two indigenous cases of plague occurred in the city of Madras. Precautions against the spread of infection were strictly carried out. When the plague broke out at Bangalore, a scheme of defence was drawn up with the aid of the Sanitary Commissioner. Four plague hospitals and four segregation camps were organised and opened by the Madras Municipality. A system of surveillance and passports was adopted which aimed at keeping every passenger from infected districts under observation for ten days. The system worked fairly well, but of course, a certain percentage of arrivals altogether escaped observation and could not be traced by the sanitary staff or the police. Further precautions included a daily scrutiny of the mortality all over the town. A reward was given for each dead rat brought to a police station, The tail of each rat was cut off, to prevent the rats being brought twice, and twice daily the rat bodies brought in were removed and cremated. But the numbers brought in did not show any tendency to diminish; there was some suspicion that persons might be induced to breed them for the sake of the reward, and it was known that field rats were constantly being brought in; so the reward was reduced. In accordance with the rules of the Venice Convention, 68 vessels, arrivals from Bombay and Calcutta, were inspected, when between two and three miles from the port, and all passengers were inspected on shore prior to embarkation. No plague cases were detected.

Plague in the Madras Presidency.—The general figures are given in the table on page 108. Plague in an indigenous form first appeared in Guntakal in the Anantapur district, in the beginning of August 1898, *i.e.*, at about the same time as it attacked Bangalore, both places being probably infected from the same source, *viz.*, Hubli. From Guntakal the disease spread to other parts of the Anantapur district and to the districts of Bellary and Kurnool. The epidemic was then rapidly extending in Mysore; and the districts of Salem and North Arcot, which are nearest to the infected portion of that province, were attacked early in December 1898. The Sanitary Commissioner notes that in no instance was a case of plague reported as having originated from infected articles received from any locality outside the presidency. The origin of the disease was always found to be due to human beings suffering from the disease arriving from an infected locality. It was not till areas having close *passenger* traffic with Mysore became infected that the Madras presidency fell a victim to indigenous plague. The measures of railway and ship inspection dated from early in 1897. The object of the methods adopted was to ensure that arrivals by road, rail, or sea should be subjected to surveillance for a period of ten days to *whatever part of the presidency they proceeded.* This was secured by the giving of a document under the Additional Regulations, requiring the persons to present themselves before certain local authorities appointed in municipal and rural areas—a method familiarly known as the "passport system." Considering the number of localities into which plague was imported and the number of times it was imported into

one place, the Sanitary Commissioner thinks this method was very effectual; though it has been objected by others that the system was not and could not be thoroughly carried out, and that there may have been other circumstances that prevented the plague from spreading. In all the railway inspection stations opened up to the end of 1898, 1,792,603 passengers were examined. Of these, 9,633 were detained for observation. The chief measures for combating an outbreak of plague were the entire evacuation of the infected locality at an early stage of the epidemic; the removal of the people of the infected area to temporary shelter in the open air, and the stoppage of all direct communication between them and their houses and the surrounding healthy villages until the disease had abated; the thorough disinfection of houses by means of sepoys or trained coolies under efficient supervision. The greatest success was obtained where these measures were carried out thoroughly, and the Sanitary Commissioner remarks that evacuation of indigenously affected areas was found, as in all epidemics of this disease that history has recorded, to be the best sanitary measure. Early in September 1898 orders were issued to start *voluntary* inoculation by Haffkine's prophylactic both in the town of Madras and in the presidency where there were commissioned medical officers. Up to December, 5,685 inoculations were performed in the city and 10,532 in the presidency, making a total of 16,217. With right, however, the Sanitary Commissioner consistently opposed advice tendered to government from time to time to neglect or abolish necessary sanitary measures in favour of inoculation alone.

Plague in Hyderabad State.—The figures for Hyderabad will be found in the table on page 108. The following is shortened from the report of the Plague Commissioner:

In 1898 there were two epidemics of plague in the Hyderabad State. The first began in the cold weather 1897–98, and was confined to the western border of the State. It reached its height in February, during which month there were 616 cases with 545 deaths; and died down in May and June, the months in which the people sleep outside their houses. The second epidemic began in September, and reached its maximum in November, when there were 1,442 cases and 1,228 deaths. In both epidemics villages in the vicinity of rivers, nullahs, and tanks, were more affected than those situated on high dry land; plague was confined almost entirely to black cotton soil districts; plague occurred principally in districts in which salt is manufactured from the soil. The infection appeared to be spread entirely by human agency. The infection having been conveyed into a house, the house itself becomes infected. The virus is deposited in the floors, the dust of which constitutes the principal medium by which the infection is propagated from one human being to another. Evacuation proved to be the only measure which arrested the progress of the epidemics. After 21 days in camp without cases or deaths, the villages were disinfected, and the inhabitants were then allowed to return to their homes. The mud floors of every house were dug out to a depth of from one and a half to two inches, the dug out portions were removed to a kiln outside the house, and burnt to ashes, and the floors were remade with fresh field earth. This process, and no other was employed, was carried out by the villagers themselves at their own cost. Detention camps were in full operation at the principal stations on the railways leading into Hyderabad throughout the year. Search parties marched from Hyderabad along every road leading to the infected frontiers, and searched every town and village *en route* for cases of plague, a reward of ten rupees having been offered for each case discovered. Experimental work was carried out in the temporary laboratory of the Hyderabad Medical School by Dr. Mullanah and his assistants.

Plague in Rajputana.—In Rajputana occurred 8 imported cases with 7 deaths and 140 indigenous cases with 117 deaths. The indigenous cases all occurred in the Sirohi State, the village of Kalindri being the most severely affected, and after it Teuri and Sheudial, while the remaining village, Wardra, had only 8 cases with 7 deaths. The monthly distribution of the disease is given in the table on page 108.

The Rajputana border has been extensively exposed throughout the Bombay epidemic to plague infection on account of its position. Moreover, the enterprising character of the Marwari takes him all over India to engage in trade, while he keeps up house and family connections in Rajputana. Consequently, when plague broke out in Bombay and the Deccan, the Marwaris returned in thousands, and extensive observation camps had to be arranged all along the lines of rail and road, as well as outside the cities, towns, and villages throughout the province. Platform inspections of all passengers from infected areas were carried out at Abu Road, Ajmere, and Bandikui; and all passengers who alighted at Rajputana, at stations on the Rajputana Malwa or the Jodhpore-Bikanir Railway were regularly examined, and segregated if found to be suffering from suspicious fever or if likely to endanger the public health in entering the villages. The imported sick and their attendants were carefully isolated in separate hospital camps, and when a patient died or recovered, everything, including the hut in which the case had been treated, was burned. In the summer of 1897 camps were started at the different railway stations for detaining arrivals from plague-infected districts. It was owing to the native officials

in charge of one of the camps having failed to carry out, in the case of a rich bania, the duties entrusted to them, the plague was introduced into the Sirohi State. In the middle of November 1897, this wealthy Seth found his way into the village of Teuri in the Sirohi State, and died there of plague. His funeral was well attended, and it was very soon followed by an outbreak of indigenous plague in this and three other villages adjacent. The villages were early vacated and disinfected, and the outbreak seemed to stop; but the weather was extremely cold at the time, and the people could not be kept out of their houses, so other cases soon occurred after re-occupation, and at the same time Poona refugees were attacked in the town of Kalindri, which had a population of over 4,000 and was only two miles distant from one of the villages early infected. Plague was at first confined to Poona refugees and their families and connections, but it afterwards spread to others in the towns, and to some of those residing at their wells some distance away. As soon as the recrudescence took place, the towns were all again promptly vacated and the people kept out in camps. The encampments were widely scattered over the fields. The huts were burnt and the sites were changed when cases occurred in them, those exposed to infection were freely disinfected, and the sick and their attendants were carefully segregated. Nevertheless, cases continued to occur till the hot weather had well set in. The nature of the disease was recognized by the villagers, who call it *chua ka rog* (rat's disease). The infected villages were entirely evacuated by the 20th January, after which date only officials were allowed to enter. The disease continued at Kalindri in epidemic form until the end of February, and sporadic cases occurred up till the 16th March. After that date three suspicious deaths were noted, and all precautions were taken as for plague. The last attack in Teuri occurred on 31st January, and in Sheudial on 2nd February. These two villages are much smaller than Kalindri, and so more easily controlled. But the early disappearance of plague from them is to be explained chiefly by the fact that there was not such a strong opposition to going into camp, and the people were moved out ten days before those of Kalindri. After an interval of a week, allowed for free ventilation, the plague houses were disinfected with perchloride of mercury solution (1 in 1,000). Then the floor of every house was dug up, and the earth carried outside and burnt. Lastly the interior of every house was thoroughly lime-washed. The houses remained unroofed until after the re-occupation of the villages on 23rd April. Excellent work was done by the Sirohi Durbar. When it is seen how plague spread elsewhere, it seems no exaggeration to say that the vigilance of the Durbar saved from a general epidemic not only the State of Sirohi but the whole of Rajputana.

Plague in Central India.—There were no indigenous, only imported, cases in the Central India Agency, either found in the trains at platform inspection stations, or, as the case in Bhopawar, imported from a plague-infected area.

Plague in Baluchistan.—The 18 deaths from plague all occurred in persons who contracted the disease in Kurrachee, and who fled from there into the Las Beyla State. There were no other cases in Baluchistan.

Plague elsewhere.—There was no plague in Burma, Assam, Coorg, or Berar. Arrangements were made to prevent the entrance of the disease into those provinces, and to fight it if it did effect an entry.

Fevers.

The fever-mortality ratio of India for 1898 was considerably below that of 1897, as well as that of the five-year period 1893–7; and the number of deaths fell from 5,026,725 in 1897 to 3,866,650. The maximum months of death were November, October, and December, and the minimum July, February, and June. The highest ratios were those of Coorg and the North-Western Provinces and Oudh, and the lowest that of Madras. The greatest reduction of ratio as compared both with 1897 and with 1893–7 was in the Central Provinces. Except in four provinces, the rural mortality was higher than the urban, the North-Western Provinces and Oudh being, as usual, one of the exceptions. Disregarding Ajmer-Merwara, the highest rural district ratio in India was that of Naini Tal in the North-Western Provinces; and the highest town ratio was that of Belgam in Bombay. No districts and only four towns in India were free from fever-mortality.

The following table, which is believed to include plague, may be consulted not only for this, but also for the succeeding paragraphs dealing with fevers in the individual provinces :—

Statement showing the deaths from Fevers registered in the different Provinces by Months during the year 1898.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL.	RATIO OF DEATHS PER 1,000 OF POPULATION.

* Excluding Zamindaris.

Sale of Quinine at Post Offices.—In Bengal there was a decrease of 3,610 parcels of quinine sold, each parcel containing 102 five-grain pice packets. The decrease, it is said, was most likely due to the exceptional healthiness of the year, and consequently to the demand for quinine being less.

In Assam the sale of quinine is said to have been on the whole satisfactory, though the vaccinators are not considered good mediums for its sale; and it is suggested that in future the secretaries of village schools should also be employed for the purpose.

Quinine is now sold at all post offices, and by all the vaccination staff in the North-Western Provinces and Oudh. In addition large quantities were sent to magistrates of districts who had found the amount in hand for gratuitous distribution insufficient. Altogether 10,604 packets were issued, the distribution being made from the district jail, Aligarh.

No statistics are given for the Punjab, but with regard to various districts it is mentioned that gratuitous distribution was made through the vaccination staff, the police, and headmen of villages.

The Central Provinces, Berar, Bombay, and Madras do not appear to have furnished particulars of quinine sales.

The sale of quinine powders continued to be appreciated by the public in Coorg, and 34,742 were sold by the post offices.

In Lower Burma 2,103 pice packets were distributed during the year. The Sanitary Commissioner remarks that the scheme for the distribution and sale of quinine does not appear to make satisfactory progress, and that its success or otherwise rests primarily with the higher district officials. He discusses the chief obstacles to success and their remedies.

Bengal.—In Bengal the mortality attributed to fevers was below that of the previous year, and below the mortality of the quinquennium as a whole. The statistics will be found in the above table. The maximum months were November, January, and December, and the minimum June, July, and February. Each month except January had a smaller number of deaths than the corresponding month of the preceding year. The Sanitary Commissioner remarks that the year was a generally healthy one, and that there was a plentiful outturn of crops almost everywhere. The highest rural district ratio was that of Noakhali, followed by those of Dinajpur, Jalpaiguri, Rajshahi, Faridpur, Purneah, and Malda; and the lowest was that of Puri. The fever at Rajshahi seems to have been partly influenza, and that at Malda was ascribed to prolonged inundations.

The opinion that the effect of short rainfall on the public health depends to some extent on the character of the country was supported by the answers of civil surgeons to inquiry on the point. Thus, rain-floods are more apt to be beneficial in high-lying than in low-lying tracts. With regard to the effect on health of jute-steeping the opinion of civil surgeons was found to be divided. The Sanitary Commissioner sums up as follows :—

It is extremely difficult to estimate to what extent jute-steeping acts as a factor in increasing the fever mortality of Bengal. The water of tanks and pools in which jute is steeped is seriously polluted and rendered unfit for human consumption, and the stench which emanates from the decomposing jute vitiates the surrounding atmosphere ; but the extent to which these two factors affect the public health depends, on the one hand on the extent to which the water thus polluted is used for drinking or domestic purposes, and, on the other, to the proximity to dwelling houses of those places in which the jute is steeped ; in other words, it depends on local conditions. In Eastern Bengal, where jute is most extensively grown, a large part of the country is subject to inundation, and during the period (generally from July to September) when jute-steeping is carried on, the rivers are overflowing and washing away everything, thus considerably diminishing the evils of water contamination. It is also noticeable that the fever mortality in all these districts is as a rule low during June, July, and very high during October to January.

The highest town ratio was that of Malda in the Malda district, and the next that of Kumarkhali in the Nadia district ; and the lowest ratios, in order, those of Kendrapara in Cuttack, Purulia in Manbhum, and Jhalakati in Backergunge.

Two deaths occurred among European seamen, one from enteric fever ; and forty in the native floating population. The ratio in both cases was below that of the preceding year.

Assam.—The Assam statistics of fevers are given in the table on page 119. The mortality ratio, though somewhat above that of the quinquennium, was much below that of the preceding year. November, July, and December were the maximum months, and February, March, and April the minimum. There was a reduction in the number of deaths in all months, except January and February, the greatest reductions being in June and July. The highest rural district death-rate was that of Nowgong, and the next that of Goalpara ; while the lowest was that of Sibsagar. The Sanitary Commissioner mentions that tha Sibsagar and Lakhimpur districts always show the least mortality from fevers, but that they are being reached by the wave of epidemic malarial poisoning a year after its attack on Cachar and Sylhet. The highest town ratio was that of Golaghat in Sibsagar, and the lowest that of Shillong.

The number of deaths recorded as from *kala azar* was less by 2,140 than in 1897, but more than in any of the three years preceding that. The Sanitary Commissioner writes :—

These 16,472 cases are included in the total of 104,963 cases, reported as due to fevers, whence it appears that nearly one-sixth of the total loss from fevers of all sorts is due to this scourge. The bulk of the cases are reported, as in former years, from the Nowgong district, many whole villages in which have no doubt been entirely depopulated or deserted ; but still I must say that I consider the figures as they stand to be utterly unreliable. I fully agree with Colonel Stephen that many, indeed the great majority of deaths which in former years would have been registered under ordinary fevers, are now returned as *kala azar*. It is impossible to suppose that in 1898 of the 11,887 persons who died from fevers of all sorts in this district, 10,515 were sufferers from *kala azar* while the ordinary malarial fevers of the country caused only 1,372 deaths. It is impossible to review satisfactorily figures which are so hopelessly inaccurate. So much has been written by officers specially deputed to investigate and report on this disease, that I refrain from saying more than that it appears to be gradually dying away from the province as a whole, and especially so from the Lower Assam districts, such as Goalpara and Kamrup, while it may possibly be slightly increasing in Darrang, and its invasion into Sibsagar is feared. Special precautions are now being taken to treat all suspicious cases occurring, and, if possible, to prevent its spread in this latter district ; though it is to be feared that both it and Lakhimpur will suffer in their turn.

North-Western Provinces and Oudh.—Mortality from fevers in the North-Western Provinces and Oudh in 1898 was much less than in 1897, and considerably less than the mortality for the quinquennium as a whole, as may be seen in the table on page 119. The highest numbers of deaths occurred in October, November, and December ; and the lowest in February, July, and March. Every month, except June, saw a reduction, as compared with the corresponding month of the previous year. The Sanitary Commissioner states that the course of the disease was normal, and presented no peculiar features. The highest rural district ratio was that of Naini Tal ; and next in order were the ratios of Bareilly, Pilibhit, Saharanpur, Bulandshahr, and Mainpuri. All those rural districts have usually high ratios. Excluding Ajmer-Merwara, the ratio of Naini Tal was also the highest rural district ratio in India ; and next to that of Coorg the general rural mortality was the highest in India. The highest town ratio was that of Manglaur in the Saharanpur district ; and Najibabad, Ghaziabad, Jalesar, Muzaffarnagar, Gonda, Aonla, Sirdhana, Sikanderabad, Mainpuri, and Gangole had ratios above 35 per 1,000. The

lowest town ratio was that of Nawabganj in the Bara Banki district. This province had the highest general urban mortality from fevers in the whole of India, and it was one of the four provinces that showed a rural mortality lower than the urban.

Punjab.—In the Punjab fever mortality was slightly reduced as compared with that of the previous year and with that of the quinquennium as a whole. The figures are given in the table on page 119. The months that had most deaths were November, October, and December, and those of fewest March, February, and July. Each of the first eight months of 1898 had more, and each of the last four fewer, deaths than the corresponding month of 1897. The highest rural district ratio was that of Dera Ismail Khan, and the lowest that of Simla ; the highest town ratio that of the Dajal in the Dera Ghazi Khan district, and the lowest that of Talamba in the Mooltan district. Palwal in the Gurgaon district, Lakki in the Bannu district, and Bhakkar and Dera Ismail Khan, both in the Dera Ismail Khan district, had also ratios over 30 per 1,000.

Central Provinces.—The statistics of fever mortality in the Central Provinces are to be found in the table on page 119. The mortality was nearly two and a half times less than in 1897, and more than one and a half times less than the mortality of the quinquennium as a whole ; and no other province showed so great a reduction. Every month of the year shared in the reduction, but it was greater from June onwards than in the first five months. The maximum months were January, October, and May, and the minimum July, June, and August. The year was one of recovery from the effects of privation and famine. The highest rural district ratio was that of Nimar, the next that of Burhanpur, and the lowest that of Sambalpur. Of town ratios the highest was that of Burha in Balaghat, the next that of Bankheri in Hoshangabad, and the lowest that of Narkar in Nagpur.

Berar.—The fever mortality of Berar, as may be seen in the table on page 119, was less than half that of the preceding year, and somewhat more than half that of the quinquennium as a whole. The highest numbers of deaths occurred in November, December, and January, and the lowest in June, July, and May. The reduction was greatest in the months May–October ; but January and February were the only months in which there was no reduction. The Sanitary Commissioner ascribes the lessening of fever mortality to reduced temperature, humidity, and rainfall. Berar was one of the four provinces that had the rural mortality below the urban. The highest rural district ratio was that of Wun, and the lowest that of Buldana ; the highest town ratios those of Ellichpur Civil Station in Ellichpur and Wadegaon in Akola, and the lowest town ratio that of Karajgaon in Ellichpur.

Madras.—The table on page 119 shows that the fever mortality of Madras in 1898 was lower than in 1897 and lower than that of the quinquennium as a whole, and that it was lower than that of any other province. The months of maximum death-numbers were January, December, and July, and those of minimum death numbers April, October, and September. In the first three months of the year there were more deaths than in the corresponding months of 1897, but in all the other months fewer, the reduction being greatest in the last quarter of the year. The Sanitary Commissioner says :—

> It is a trite statement, but one necessary to be held in mind, that under the head of "Fevers" the majority of all affections in which pyrexia is a prominent symptom are likely to appear, as a sequence of the present system of registration and state of medical advance of the country. Nevertheless, it is safe to assume that the greater number of deaths so registered are due to malaria.

He mentions cases in which, to escape inquiry, cholera was registered under "Fevers," fever under "Other causes," and plague under "Other causes." The Sanitary Commissioner also indicates his belief that the period of greatest mortality from fever is that which immediately follows the greatest fall of the subsoil water level, and heralds a commencing rise ; and that a fall subsequent to a great rise will be followed by increased mortality.

Of all the provinces Madras had the lowest rural mortality. The highest district ratio was that of the Nilgiris, and the lowest that of Tanjore. Madras had a lower urban mortality than any other province. The highest town ratio was that of Kampli in Bellary, and the lowest that of Rajahpalaiyam in Tinnevelly.

Coorg.—In Coorg the fever mortality, though higher than that of the decennium as a whole, was much reduced from that of the previous year. Of the provincial ratios that of Coorg was the highest; and Coorg had also the highest rural mortality. The reduction was greatest in June, July, and the months of the final quarter; but all the months except the first three shared in it. January was the maximum month and November the minimum. Naujarajapatna had the highest rural district ratio, and Kodlipett the highest town ratio.

Bombay.—As may be seen in the table on page 119, the Bombay fever death ratio was considerably below that of the preceding year and that of the five-year period. Every month of the year had fewer deaths than the corresponding month of 1897, the reduction being greatest in June and July. Deaths were most numerous in October, November, and December, and least numerous in June, July, and May. The figures shown in the tables include plague. If it were excluded, there would remain 216,324 deaths ascribed to fever, giving a ratio of 11·49 per 1,000. Such a ratio would class the year as one of the healthiest in the last eleven years, the people being in a state of rapid recovery from the famine of the previous year. The Sanitary Commissioner says:—

> With the agency at our disposal for the registration of deaths, and in a country where so many diseases are by the people called fever, it is inevitable that many diseases must be returned under the head of "fever" which do not rightly belong to this heading. This has always been the case, and, although these fever deaths cannot be relied on as being all due to fever, they can, when taken for a number of successive years, give an indication as to the prevalence or otherwise of the common fevers of the country. The carrying out of plague measures in some of the towns of the presidency has led to very much more accurate registration in them.

Bombay was one of the four provinces that had a rural ratio lower than the urban. The highest rural district ratio was that of Dharwar, the district invaded in greatest force by plague, that of Broach coming second; and the lowest that of Ahmednagar. The highest town ratio, which was also the highest in India was that of Belgam, a city attacked by the plague. The same explanation applies to the high ratios of Belgam Cantonment and of Gokak. The lowest town ratio was that of Ahmednagar Cantonment.

Lower Burma.—Lower Burma was the only province, besides Mysore, in which the death ratio from fevers was higher than both the ratio of 1897 and the period ratio for the quinquennium. The elucidatory figures will be found in the table on page 119. The increase was confined to the first six months of the year, each of the last six months showing a decrease. January, August, and December saw most deaths, and May, April, and June fewest. The Sanitary Commissioner considers that if it were possible to differentiate diseases by a professional agency possessed of some degree of medical knowledge, probably not less than 50 per cent. of the fatality ascribed to this cause would come under other heads. The highest rural district ratio was that of Akyab, the ratios of Sandoway and Toungoo not being far behind, and the lowest that of Hanthawaddy. Shwegyin, followed by Myaungmya, had the highest town ratio, and Danubyu the lowest. The fever mortality of 9 towns of Upper Burma taken together was 8·59 per 1000, which is very near the urban mortality of Lower Burma.

Dysentery and Diarrhœa.

The mortality for India from dysentery and diarrhœa was reduced by 47 per cent. as compared with that of 1897, and 20 per cent. as compared with that of the quinquennium as a whole. The highest numbers of deaths occurred in the months of August, January, and September, and the lowest in April, March, and June. Every month, except January, showed a reduction as compared with the corresponding month of 1897, the diminution being greatest in the four months July–October.

The highest provincial death-rates were those of Berar, Assam, and Bombay; the lowest those of the North-Western Provinces and Bengal. The ratio of every province showed a decrease, except that of the Punjab, which was unchanged, and that of Ajmer-Merwara, which rose. The last-named province was the only one of which the ratio was increased as compared both with that of 1897 and with that of the quinquennium. The decrease as compared with the preceding year was in the case of the Central Provinces, and the greatest as compared with the five-year period in Berar. The decrease for India was connected with the return of the seasons to the normal, and the consequent passing away of famine and privation.

The following statement illustrates not only what has just been written, but also the succeeding paragraphs upon bowel complaints in the different provinces :—

Statement showing the Deaths from Dysentery and Diarrhœa registered in the different Provinces by Months during the year 1898.

Province.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total. 1898.	Ratio of deaths per 1,000 of population. 1898.	1897.

* Excluding Zamindaris.

Ajmer-Merwara was the only province that had a percentage of rural districts without mortality ; but, on the other hand, the same province and Assam were the only ones in which there were no towns without mortality. The highest rural district ratio was that of Lakhimpur, and the highest town ratio that of Golaghat, both in Assam. The general rural mortality was highest in Berar and Assam, and the general urban mortality in Assam and Coorg. Only in Berar was the rural mortality greater than the urban.

Bengal.—In Bengal the mortality from dysentery and diarrhœa was reduced as compared both with that of 1897 and with the period ratio of the quinquennium. The statistics may be obtained from the above table. The reduction affected every month except January and February, and was greatest in the period July–November. According to the Sanitary Commissioner, the large falling-off in the mortality was evidently due to the plentiful outturn of crops almost everywhere during 1897, which enabled the people to obtain wholesome food ; and it is noticeable that almost all the districts that were affected by the late famine show a smaller mortality from this cause during 1898. The highest rural district ratio was that of Darjeeling, and that of Howrah came next, followed by those of Balasore and Puri : all being rural districts which always return high mortalities. Uttarpara in the Hooghly district had the highest town ratio, followed, in order, by Serampore, Garulia, Baidabati, Bally, Howrah, Hooghly-Chinsura, and Dacca.

There were two deaths among European seamen and four in the native floating population, the respective ratios being 1·62 and 0·15.

Assam.—The statistical points of most importance as to the mortality in Assam from dysentery and diarrhœa are given in the above table. It was diminished both in comparison with that of 1897 and with that of the quinquennium as a whole. Every month showed a decrease, except January. The maximum months were October, July, and June, and the minimum March, February, and April. The Sanitary Commissioner, in pointing out the remarkable variations of mortality shown by the different districts, says that he knows of no difference in the vital conditions affecting the inhabitants of the upper and lower stretches of the great Assam river which could possibly produce them. The highest rural district mortality, which was also the highest in India, was that of Lakhimpur, and the lowest that of Goalpara. Golaghat, in the Sibsagar district, had the highest town ratio in Assam and in India, and of all the provinces Assam had the highest general urban mortality ratio. The lowest town ratio was that of Jowai in the Hill district.

North-Western Provinces and Oudh.—The mortality from dysentery and diarrhœa in the North-Western Provinces and Oudh, as may be seen in the table on page 123, was two and a half times less than that of 1897, and less than half the period ratio of the quinquennium. In every month of the year the reduction was great. The months of most deaths were October, August, and September, and those of the fewest March, February, and April. The highest rural district ratio was that of Garhwal, that of Almora being nearest to it, and that of Mainpuri lowest. Kashipur in the Naini Tal district had much the highest town ratio, the next in order being Hathras in the Aligarh district. The lowest town ratio, which was also the lowest in India, was that of Bindraban in the Muttra district.

Punjab.—The Punjab had a mortality ratio from diarrhœa which was exactly the same as in the previous year, and exactly the same as the ratio for the quinquennium as a whole. Reference may be made to the table on page 123. The greatest number of deaths occurred in October, September, and November, and the smallest in February, March, and April. Each of the first nine months saw an increase, each of the last three a decrease. The highest rural district ratio was that of Simla, which, like Gurdaspur, Gurgaon, and Delhi, usually has a high ratio ; and the lowest that of Hazara. Balabgarh, in the Delhi district, had by far the highest town ratio—those of Pind Dadan Khan in the Jhelum district, and Khanpur in the Hoshiarpur district being also high—and Muktsar in the Ferozepore district the lowest.

Central Provinces.—As the table at page 123 shows the Central Provinces had a mortality from dysentery and diarrhœa nearly seven times less than that of 1897, and more than two and a half times less than the period ratio of the quinquennium. The reduction in this province was greater than in any other, and affected every month of the year. The maximum months were January, August, and September, and the minimum December, November, and June. The Sanitary Commissioner views this marked decline in the death-rate from bowel complaints as evidence of the complete disappearance of famine and privation from among the people. The highest rural district death-rate was that of Sambalpur, and the lowest that of Bhandara. Seoni in the Hoshangabad district, Murwara in the Murwara district, and Damoh in the Damoh district, had the highest town ratios, and Umrer in the Nagpur district the lowest.

Berar.—In Berar the mortality from dysentery and diarrhœa was only about one-third of that of 1897, and about one-half the quinquennial period mortality. No other province showed so great a reduction from its quinquennial figure. The table on page 123 show the statistics. The months of greatest death-occurrence were September, August, and January, and those in which fewest deaths took place were June, May, and February. Of all the provinces Berar had the highest general rural mortality ; and it was the only one in which the rural mortality was greater than the urban. The highest rural district ratio was that of Ellichpur, and that of Wun the lowest. The Sanitary Commissioner suspects that in the Wun district deaths from dysentery were reported and classed as deaths from fevers. The highest town ratio was that of Nandura in the Buldana district, the next that of Karajgoan in the Ellichpur district, and the lowest that of Senderjana in the Amraoti district.

Madras.—Madras in 1898 recorded a mortality under this head which, while considerably below that of 1897, was somewhat higher than that for the five-year period. Particulars may be studied in the table on page 123. In all the months, except February and December, there was reduction in the number of deaths, but the reduction was greatest in the four months July–October. December, November, and January saw most deaths ; April, March, and May fewest. The Sanitary Commissioner believes that the diminution of mortality may fairly be regarded as due to improved dietary of the people following the fall in the price of grain. The highest rural district ratio was that of Chingleput, and the lowest that of Madura ; the highest town ratio that of Tuticorin in the Tinnevelly district, and the lowest that of Palin in the Madura district. Regarding Tuticorin, Cochin, Madras, and Coonoor, the Sanitary Commissioner mentions certain circumstances of soil and water pollution as explaining their high death-rates.

Coorg.—Coorg, as may be seen in the table on page 123, recorded a considerably reduced mortality from dysentery and diarrhœa. The reduction affected every month, but was most marked after March. Yedenalknad had the highest rural district ratio, and Veerajendrapett much the highest town ratio.

Bombay.—The mortality ratio of Bombay, under dysentery and diarrhœa, though lower than that of the previous year, was somewhat higher than the ratio for the quinquennium as a whole. Some statistical details will be found in the table on page 123. There was great decrease in each of the five months July–November, decrease in April–June and December, increase in February and March, and great increase in January. The maximum months were August, September, and October, and the minimum June, May, and February. In the opinion of the Sanitary Commissioner these bowel complaints are chiefly due to the after-effects of the famine. The highest rural district death-rate was that of Sholapur, the district which was most severely affected by the famine, as well as the one in which it continued longest. Nasik came next, and Upper Sind Frontier last. Nandurbar in the Khandesh district had the highest town ratio, and there were other high ratios in the same district; while Kaira in the district of the same name had the lowest.

Burma.—The table given on page 123 shows that Lower Burma had a mortality from dysentery and diarrhœa below that of the preceding year, but above that of the quinquennium as a whole. The months of most deaths were July, June, and August, and those of fewest December, March, and November. Compared with the corresponding months of 1897, January, May, June, October, and November showed increase, the others decrease. The highest rural district ratio was that of Thaton, the next being that of Tavoy, and the lowest that of Sandoway. Ma-ubin had the highest town ratio and Shwedaung the lowest. Nine towns of Upper Burma together gave a ratio of 0·98, much lower than the urban mortality of Lower Burma.

Injuries.

The deaths recorded under "injuries" are shown in the following statement.

When compared with the similar table in the report for 1897, it may be gathered that there was an increase in the number of deaths caused by snakes and wild beasts in several provinces, but especially in Mysore. (The figure printed opposite Madras as 260 in the 1897 table is a press mistake for 2,260.) The Sanitary Commissioner of Bombay notes that snake-bites were most frequent in the six months May–October, and in the districts of Ratnagiri, Hyderabad, Shikarpur, and Thana. In the Punjab there were 147 deaths from hydrophobia against 129 in the previous year. There was a great decrease of suicide in the Central Provinces after the increase that occurred in the time of famine and privation. In Assam a steady increase of suicide is noted by the Sanitary Commissioner. In Bengal in 1897 there had been an unusually high number of accidental deaths, due to the loss of life in the Chittagong cyclone; hence the diminution in 1898. In Bombay more females than males died by drowning, but more males than females by the other forms of injury.

Statement showing details of Deaths from Injuries registered in the different Provinces during the year 1898.

Province.	Population under registration.	Details of Deaths from Injuries.			Total.
		Suicide.	Snake-bite or killed by wild beasts.	Wounding, accident, and other injuries.	
Bengal	71,069,617	3,599	12,403	16,458	32,460
Assam	5,021,084	128	256	1,288	1,672

Total	218,041,859	10,342	28,113	56,836	95,291

* Excluding Zamindaris.

All Other Causes.

The number of deaths recorded under this head was 1,376,725 against 1,476,672, and the ratio per 1,000 of population was 6·31 against 6·79. Every month of the year shared in the diminution except November and December, which showed decided increases. The maximum months were December, November, and October, and the minimum April, June, and May. The greatest decreases were in Berar and the Central Provinces, and the greatest increase in Bombay. The Sanitary Commissioners of Bombay and the Punjab mention that greater accuracy of return brings under this head cases which would formerly have been registered under fever. The former officer notices the tendency to put under this head cases of plague, so as to avoid the inquiry that might have been aroused by their return as fever. The same thing was noticed to a smaller extent in Madras.

Vaccination.

During 1896–97 the total number of persons vaccinated among the civil population of British India was 8,019,836 ; in 1897–98 the number fell to 7,829,983 ; and in 1898–99 the total showed a further decrease of upwards of three hundred thousand, and was only 7,497,597. The causes of the falling off in 1897–98 were mainly the presence of famine and plague, and although the effect on vaccination in 1898–99 of the recent famine was confined to diminished birth-rates in some of the provinces, the other cause was still unhappily persistent.

The actual presence of plague and the fear of its invasion have caused the diversion of the services of officers and subordinates ordinarily occupied in supervising and carrying on vaccination, while, among the people in many places, apart from the disturbance of the ordinary conditions of life, there is the unfounded dread that vaccination is being used as a cloak for anti-plague inoculation. So great was the terror of this in Coorg that vaccination had to be stopped altogether from November to March, and the operations performed during the year numbered only about half those performed in 1897–98.

The provinces in which the decrease occurred were Madras, Bombay, Bengal, the Punjab, Assam, and Coorg ; in the other provinces the number of operations was greater than in the preceding year. In Madras, Bombay, and Coorg, the falling off was due in one way or another to plague. In Bengal, in addition, there was the introduction of a more perfect method of vaccinating. In the Punjab a new system of itinerating among the vaccinators was misunderstood, and the vaccinators did not work well. In Assam, although malarial fevers were unusually severe in a part of the province, the chief cause of the falling-off was the unsatisfactory working of many of the staff.

Both primary operations and re-vaccinations were fewer than in 1897–98, the former falling from 7,186,888 to 6,913,977, and the latter from 618,065 to 583,602. The degree of success in primary operations was, however, somewhat higher in 1898–99 than in the preceding year, 94·02 per cent. having succeeded against 93·91 ; re-vaccinations, on the other hand, were less successful, 63·71 per cent. as compared with 64·44 per cent.

Among the different provinces the percentages of success varied greatly ; in primary operations, from 98·84 in Assam to 89·6 in Madras, and in re-vaccinations, from 93·4 in Assam to 23·1 in Berar. Extreme differences in results must be due in the main to divergence in the interpretation of the term " successful."

The percentages of success obtained by the staffs of dispensaries ranged, in primary operations, from 96·75 in Bombay to 72·80 in Coorg, and in re-vaccinations, from 90·63 in Assam to 52·96 in Bengal.

The ratio of the total population protected during the year fell from 31·53 per 1,000 in 1897–98 to 30·30 per 1,000 in 1898–99, the provincial ratios varying between 54·41 per 1,000 in Burma and 26·74 in Bombay.

As in the preceding year, the average number of operations performed by each vaccinator was highest in Berar, 3,020, and lowest in Bengal, 586.

Although there was a falling-off in the number of infants protected in Madras, Bombay, Bengal, Assam, Berar, and Coorg, yet the total in all provinces taken together was greater in 1898–99 than in 1897–98, rising from 2,815,592 in the latter to 2,853,132 in the former. The percentage of the total children born, estimated at 40 per 1,000 of the entire population, was 31·37 per cent. as compared with 30·95 per cent. in the preceding year, and ranged from 60·31 in Berar to 7·38 in Coorg.

The number of children between one year and six years of age who were successfully vaccinated fell from 3,172,881 in 1897–98 to 3,008,037 in 1898–99, the decrease occurring in Madras, Bengal, the Central Provinces, Assam, and Coorg.

The following statement shows in outline the working of the Department in the different provinces in 1898–99 and in the preceding year :—

Comparative statement of Vaccination in the different Provinces of India, excluding Ajmere-Merwara, in 1897–98 *and* 1898–99, *together with the death-rates from Small-pox during* 1897–98.

PROVINCE.		Population.	NUMBER OF VACCINATIONS PERFORMED. Primary.	Re-vaccinations.	TOTAL.	PERCENTAGE OF SUCCESSFUL CASES. Primary.	Re-vaccinations.	Persons successfully vaccinated per 1,000 of population.	Ratio of deaths from small-pox per 1,000 of population during the calendar years 1897 and 1898. * Refers to special Vaccination Establishment only. † Including tea gardens.
‡ Calculated on figures taken from Sanitary Reports.

Animal Vaccinations.—In every province bovine lymph, either fresh or preserved, was largely used ; in Madras, Burma, Assam, Berar, and Coorg exclusively, or almost exclusively.

In Madras the highest ratio of success was obtained with fresh calf lymph, but excellent results were obtained with both lanolinated and glycerinated lymph, the use of which throughout the Presidency is exhibited in the following statement :—

		Glycerinated Lymph. Number of cases.	Glycerinated Lymph. Percentage of success.	Lanolinated Lymph. Number of cases.	Lanolinated Lymph. Percentage of success.
In districts	Primary and secondary operations.	413,243	82·8	220,170	89·0
	Re-vaccinations.	15,742	70·4	12,111	68·4
Operations performed by dispensary staffs and medical subordinates.	Total cases...	9,258	80·1	15,213	75·1
Operations in municipalities.	Total cases...	25,500	91·2	50,205	91·3

In the preceding year higher percentages of success were uniformly obtained with glycerinated lymph than with lanolinated lymph ; but in 1898 the percentages resulting from the use of the latter were higher in primary operations in the districts and in municipalities.

In the Central provinces the manufacture of glycerinated lymph was not attended by success. In Assam, on the other hand, the product of the Shillong depôt was extraordinarily efficacious. The vaccine is pounded up with a mixture of glycerine and water "in the proportion of two parts of the solid matter, and one part each of glycerine and water, by weight." It is preserved in capillary tubes, which are sealed in the flame of a spirit-lamp. The Sanitary Commissioner, Colonel Carr-Calthrop, while admitting that this method of preservation is "troublesome, laborious, and more expensive than simple admixture with lanoline," claims for it that much less risk of contamination is involved in the use of a fresh capillary tube for each operation, than when operation after operation is performed from the same pot of lanolinated lymph.

Bengal.—During the official year 1898–99 the vaccination staff employed in Bengal, under the direction of the Sanitary Commissioner, comprised three Deputy Sanitary Commissioners, 48 Civil Surgeons, 206 native supervisors and five head vaccinators, the operators being 79 vaccinators paid by Government, 41 paid by District Boards, 241 employed by municipalities and at dispensaries, 3,362 licensed vaccinators and 1,134 apprentices. For the greater part of the year the department was worked at an extraordinary disadvantage, being without the services of the Deputy Sanitary Commissioners, as commissioned medical officers could not be spared from other duties ; so that each of the three vaccination circles was in charge of a commissioned officer for only two or three months.

The total number of operations performed throughout the province was 2,147,452, or 172,084 fewer than in 1897–98. The decrease was distributed over 35 districts and is attributed to several causes, the more important being the difficulty experienced by the licensed vaccinators in realising their fees, the plague inoculation scare, and the introduction of the practice of making six punctures, the two extra punctures being connected in some way in the mind of the masses with inoculation against plague. The practice of making six punctures has now been introduced into the province generally, and although very unpopular at first—so much so that a certain degree of relaxation of the rule had to be permitted,—opposition is gradually dying out.

The number of primary operations that succeeded was 2,045,384 as compared with 2,195,509 in 1897–98, but the degree of success claimed was somewhat greater, 97·99 per cent. against 97·87. This high ratio does not, however, represent the facts, for vaccinators are prone to include in the returns partial successes and even absolute failures as successful cases. The number of re-vaccinations performed during the year was 60,167—a decline of 16,276 from the total of the preceding year ; while the number of successful cases fell from 49,207 to 40,520. The percentage of success was, however, higher, 67·34 against 64·36 in 1897–98. The falling-off in the number of re-vaccinations is doubtless only temporary, for in the gradual increase in the number of these operations in recent years there is evidence that the people are beginning to appreciate the security afforded by the second operation. The rise in the ratio of success, which in 1898–99 was nearly twice as high as the average of the previous triennial period, is attributed by the local officers (*a*) to the operations being done at a sufficiently long interval after the primary vaccination to allow of the passing away of the effect of the latter, and (*b*) to the primary operation having been a failure or only a partial success.

Taking the number of infants born at 40 per 1,000 of the census population of 1891, 17·66 per cent. were protected during the year, against 17·8 in 1897–98 and 15·50 the mean of the three years 1894–95 to 1896–97.

The average number of operations performed by the vaccinators was considerably less than in 1897–98, the figure falling from 650 to 586.

The work of inspection was greatly hampered by the absence of the Deputy Sanitary Commissioners : in the Metropolitan and Eastern Bengal circles, no inspections were made by them at all ; in Northern Bengal only 1,366 ; and in Western Bengal 7,627. In only two districts, Dacca and Purnea, as compared with five in the preceding year, did the inspections made by Civil Surgeons exceed 10,000 ; in seven as compared with nine the numbers ranged from 5,000 to 10,000 ; while in four districts the numbers were below 1,000. The proportion of the total operations inspected by Civil Surgeons was 8·51 per cent. against 9·34 in 1897-98, and the percentages verified by District Inspectors and Sub-Inspectors fell from 40·76 and 67·44 to 39·70 and 67·81, respectively.

Direct calf-to-arm vaccination is gradually gaining ground; the primary operations in 1898-99 numbered 206,083, an increase of 31,082 over the figure for the previous year, which was 25,681 in advance of that for 1896-97. Re-vaccinations, however, numbered only 21,632, or 7,855, less than in the previous year.

Vaccination is progressing in Bengal, but there is still much opposition to it in some districts, particularly in Behar, in Puri, and in the Tributary States of Orissa. In certain of the districts Major Dyson despairs of any effective remedy short of the introduction of the Compulsory Vaccination Act. In Puri he considers that high caste Hindu operators paid by the District Board should be substituted for the licensed men; and he suggests the starting of a vaccination school at Cuttack where operators could be trained for Orissa and the Tributary States.

Assam.—The vaccination staff in Assam working under the general control of the Sanitary Commissioner and the District Civil Surgeons comprised 18 native inspectors, 183 paid and 29 licensed operators, with seven apprentices; and was supplemented by medical subordinates attached to dispensaries and private practitioners on Tea-garden estates.

The total number of operations performed by all agencies was 258,905, a considerable falling-off as compared with the total of either of the last two years. The decline was, however, limited to primary operations and to the work of the provincial staff, and occurred in the districts of Sylhet, Goalpara, Darrang, Nowgong and Sibsagar, and the Nagar Hills. In Sylhet, where the greatest decrease occurred, it is attributed to a very severe outbreak of malarial fever, a lowered birth-rate and high mortality among infants, and in Goalpara it is said that similar influences were at work, but in the other districts it is to be feared that lack of zeal among the staff was the principal factor involved.

The number of operations performed by the paid and licensed operators aggregated 232,419, of which 208,542 primary operations and 20,113 re-vaccinations were reported to be successful. The ratios of success claimed work out to 98·84 per cent. of the primary operations and 93·84 of the re-vaccinations; but the Sanitary Commissioner commenting on the primary operations writes:—"I am of opinion that the number of cases reported as successful is too high. Vaccinators seem to report, as successful, cases in which the smallest vesicle follows the operation, notwithstanding that no trace may be visible three months afterwards. From my personal inspections, I should think primary operations were probably satisfactory in 95 per cent., partially successful in 3 per cent., and failures in about 2 per cent." And regarding re-vaccinations "the percentage reported of successful re-vaccinations, *viz.*, 93·84, is suspiciously high, and is to my mind inconsistent with a very high percentage of thoroughly successful primary vaccinations."

Operators at dispensaries did not report quite such high percentages of success; of a total of 14,271 operations, 13,226 were successful primary vaccinations and 348 re-vaccinations succeeded, the percentages of success being respectively 95·24 and 90·63.

The Compulsory Vaccination Act remained in force in 11 towns, but the aggregate number of operations performed in them continued to fall; in 1898-99 the number was 3,021 against 3,487 in the preceding year, and 4,152 in 1896-97. Notices were served on defaulters in only seven of the towns; 26 prosecutions were conducted, but only four persons were punished.

Taking the number of successful operations performed by all agencies combined, 45·02 per thousand of the population were protected during the year against 49·61 in 1897-98, and 40·62, the average of the previous quinquennium. The number of infants protected was 50,389, or about 22·36 of a hypothetical birth-rate of 40 per 1,000. This ratio, although less than that estimated in the preceding year, 25·9, is higher than the mean of the previous three years, which was 19·69 per 1,000. Although the actual number of cases inspected by Civil Surgeons was less than in the preceding year, 22,577 against 24,207, the percentage, owing to the smaller total, was higher, 9·15 against 8·87. Native Inspectors verified only 133,681 cases or 54·19 per cent., against 150,005, or 55·0 per cent. in 1897-98, the falling off being most conspicuous in Sylhet, Goalpara, and Nowgong, although in the last named small-pox was prevalent.

The percentages of the cases verified by Civil Surgeons and Native Inspectors which were found to be successful were, respectively, 95·99 and 98·73 per cent., as compared with 98·66 and 98·14 in the preceding year.

Inoculation is said to be practised in the districts of Sibsagar, Sylhet and Cachar, but not to the same extent as formerly, and no outbreak of small-pox was traced to it.

The animal vaccine depôt at Shillong was worked very successfully throughout the year, the supply from it was the largest on record and the quality of the glycerinated

lymph was all that could be desired, so that the Chief Commissioner has authorised the abandonment of further attempts to introduce the use of fresh calf lymph at district head-quarters.

North-Western Provinces and Oudh.—The supervising staff of the Vaccination Department in the North-Western Provinces and Oudh in 1898-99 consisted of the Sanitary Commissioner and his two Deputies, the District Civil Surgeons and 49 Assistant Superintendents. The average number of operators, including those paid from local funds, was 875, or nine more than in the preceding year.

The number of operations performed was 1,398,684, which, although it exceeded the total of 1897-98 by 14,024, fell short of that of 1896-97 by no less than 128,624.

The decrease was chiefly due to the employment, on duty in connection with plague prevention and the sanitation of fairs, of many of the most tactful and experienced vaccinators, the men engaged to take their places being, in many instances, untrained, and lacking the influence of the permanent employés.

The average number of operations performed by each vaccinator was almost the same as in the preceding year, 1,598·5 as compared with 1,598·9. Of the total number of vaccinations performed. 1,340,036 were primary, and 58,648 were re-vaccinations, and the percentages of success claimed were 94·96 and 79·76 respectively, against 93·74 and 68·20 in 1897-98. At dispensaries, 525 primary operations and 17 re-vaccinations were performed, the ratios of success being 90·02 and 71·43 per cent. There were 637,472 infants successfully vaccinated during the year, so that estimating the number of births at 40 per thousand of the census population, 33·80 per cent. of the children born were protected, as compared with 29·23 per cent. in 1897-98, and 30·24 the mean of the three years, 1894-95 to 1896-97.

The decline in the numbers vaccinated in the towns where the Act is in force was noted in last year's report. This year the results were still worse. Although a few more vaccinators were employed, the number of primary operations fell from 111,585 in 1897-98 to 110,515, and the re-vaccinations from 4,987 to 3,896; but there was some improvement in the quality of the work, primary cases succeeding in 1898-99 at the rate of 95·01 per cent. against 92·45, and re-vaccinations at the rate of 71·97 per cent. against 71·41.

Although one of the Deputy Sanitary Commissioners was absent, and much of the time ordinarily devoted by the other to the work of inspection was spent on duty in connection with the prevention of plague and at the great fairs, there was an increase in the number of inspections made by Deputy Sanitary Commissioners and Civil Surgeons, the percentage of the total number of operations verified rising from 6·31 in 1897-98 to 9·25; while Assistant Superintendents verified 29·40 against 26·98 per cent. Superior inspecting officers found 93·62 per cent., and inferior inspecting officers 93·38 per cent. of the cases seen by them to be successful, against 94·36 per cent. of success claimed by the vaccinators.

The supplies of lymph sent from Garhwal and Almora for starting work on the plains was of good quality, but many of the tubes sent from Tehri-Garhwal were bad, and had to be destroyed. The work done at the Lucknow depôt was satisfactory, but the same could not be said of the establishment at Allahabad.

Punjab.—In the Punjab the supervising staff, consisting of the Sanitary Commissioner, his Deputy, the District Civil Surgeons, six Divisional Inspectors, and 34 Native Supervisors remained unchanged, and the number of vaccinators was 303 against 305 in 1897-98. The number of operations performed during the year was 840,868, against 845,491 in the preceding year, and 902,413 in 1896·97. Of the total, 661,937 were primary operations and 178,931 were re-vaccinations, as compared with 631,774 and 213,717 respectively in the preceding year.

Excepting an increase, amounting to 41,117, in the number of primary operations performed by the district staff, there was a general falling off in the numbers of operations of both classes performed by all agencies. Among the causes of the decrease are said to be the failure of the vaseline lymph, difficulty in procuring calves, dislike of the vaccinators to the new system of working in groups, and carelessness on the part of the operators. All these matters have the attention of the authorities, and it may be stated that the falling off is, in part, at any rate, believed to be apparent only, since the stricter supervision by the District Inspectors has checked the too common falsification of returns. The reduction in the amount of work was most marked in the case of the special staff who performed only 62,196 primary operations against 72,031 in the

previous year, while the re-vaccinations done by them fell from 31,104 to 14,742 ; and even the latter figure is suspected by the Deputy Sanitary Commissioner to be "in excess of the actual number of operations performed." The decline in the work of the special staff is mainly due to the absence of supervision, the Deputy Sanitary Commissioner having been on plague duty for a portion of the year, but there was misconduct on the part of one of the native supervisors and some of the vaccinators, while the assistance which should have been given by certain local authorities was withheld.

The average percentage of success was somewhat higher in primary operations and lower in re-vaccinations than in the previous year, the figures being 94·84 and 58·80 in 1898–99, and 94·40 and 60·77 in 1897–98.

Returns were furnished by seven of the eight large Native States which maintain their own vaccination establishments. There were 84,547 primary operations and 42,506 re-vaccinations performed in them, the ratios of success claimed being 95·40 and 49·60 per cent. Nearly three-fourths of the operations were performed in Patiala, but the results, both as regards quantity and quality, were not so good as in 1897–98.

Estimating the number of births at 40 per 1,000 of the census population, 59·97 per cent. of the infants born during the year were protected, as compared with 57·5 per cent. in 1897–98, and 58·25 per cent., the mean of the previous three years.

Civil Surgeons verified 6·54 per cent. of the primary cases and 3·38 per cent. of the re-vaccinations, against 8·66 and 2·25 per cent. in the previous year, native supervisors inspected 60·14 per cent. and 35·21 per cent., against 61·10 and 23·73 per cent., and Divisional Inspectors 17·81 per cent. and 15·29 per cent., against 17·94 and 25·85 per cent. The ratios of success found on inspection were in all cases higher than those claimed by the vaccinators, in consequence chiefly of the latter being required to return all operations, the results of which are unknown, as failures.

The Compulsory Act was introduced into the towns of Leiah and Gujranwala during the official year ; but in most of the 18 towns in which the Act has been in force for some years past the amount of work done was comparatively small.

The vaccines used were humanized lymph, fresh calf lymph, and calf lymph mixed with vaseline. Information in respect of the success obtained with the different vaccines in the province as a whole is not given in the provincial report ; but the results obtained by the special staff were the following :—in primary cases, humanized lymph was successful in 100 per cent., fresh calf lymph in 97·55 per cent., and vaseline vaccine in 96·14 ; in re-vaccinations humanized lymph produced successful results in 87·31 per cent. of the operations, fresh calf lymph in 73·42 per cent., and vaseline vaccine in 74·13 per cent.

The depôts at Murree and Amritsar were open, respectively, from April to October, and from November to March. Only vaseline lymph paste is prepared at these depôts, and during the year 1,374 tubes were sent out from Murree and 1,792 from Amritsar. Of the total number only 53 are reported to have failed, but the results obtained with 744 are unknown

Central Provinces.—In 1898–99, as in the preceding year, the supervising staff under the control of the Sanitary Commissioner comprised the District Civil Surgeons, 28 Native Superintendents and 274 vaccinators.

With the passing away of famine, and the low birth-rate and high infantile mortality which attended it, the work of the department has improved. The total number of operations amounted to 435,174, against 384,476 in 1897–98, and the average number of operations performed by each vaccinator rose from 1,391 to 1,588. The increase was shared by the British districts and by the Native States, although in the latter re-vaccinations were somewhat fewer than in the preceding year.

In British territory the total number of primary operations was 294,289, of which 284,926, or 96·82 per cent., succeeded, and the number of re-vaccinations was 52,274 in which success was claimed in 41,377 cases, or 79·15 per cent., against 96·73 and 85·84 per cent in 1897–98.

In the Feudatory States primary operations aggregated 76,743 and re-vaccinations 11,868, the percentages of success reported being 92·86 and 95·70, respectively, as compared with 96·86 and 94·27 in the preceding year.

Besides these operations, there were in all 14,076 performed by the staff of dispensaries, or 147 less than in 1897–98. In the British districts 10,928 primary operations were performed and 1,411 re-vaccinations, the ratios of success being 94·03 and 61·45 per cent., as compared with 95·46 and 77·48, respectively, in the previous year. In the Native States there were 1,673 primary vaccinations and 64 re vaccinations, of which 91·51 and

87·50 per cent., respectively, proved successful, as compared with 90·86 and 91·38 in 1897–98.

Calculated on an estimated birth-rate of 40 per 1,000 of the census population, 44·61 per cent. of the children born during the year were protected, against 36·20 in 1897–98 and 50·29, the mean of the previous triennium.

Although in both British territory and in the Feudatory States the numbers of villages visited and operations verified by Civil Surgeons and Native Superintendents were larger than in 1897–98, yet, owing to the greater number of operations performed, the proportions seen by both classes of officers were less, falling from 18·79 and 55·45 per cent., respectively, to 17·19 and 53·35 per cent. The percentages of all cases examined by Civil Surgeons and Native Superintendents which were found to be successful were, respectively, 89·08 and 92·19, as compared with 92·40 and 93·45 in the preceding year, these figures being lower in both years than the percentages claimed by the operators.

Operations were carried on with humanized lymph, fresh calf lymph and calf lymph mixed with lanoline and with glycerine, but no figures to show the degree of success obtained with the different vaccines are given in the provincial report. It is, however, stated that the manufacture of glycerinated lymph was not at all successful.

Berar.—The provincial vaccination staff consisted of 7 Native Superintendents and 44 vaccinators, under the direct control of the Sanitary Commissioner.

The total number of operations performed was 132,903, of which 94,032 were primary and 38,871 re-vaccinations, as compared with 95,048 primary operations and 30,241 re-vaccinations, in 1897–98. The falling off in the number of primary operations was mainly due to the diminished birth-rate of the year, while the increase in re-vaccination was brought about by the special attention given to the operation in places where small-pox had broken out, and was attacking chiefly "the grown up children and adults for want of re-vaccination."

The average number of operations performed by each vaccinator, which in 1897–98 was 2,847, in 1898–99 reached the high figure of 3,020.

Of the primary operations 91,286, and of the re-vaccinations 8,989 succeeded, the percentages being, respectively, 97·1 and 23·1, as compared with 96·4 and 30·0 in the previous year.

Estimating the number of children born during the year at 40 per 1,000 of the census population, 60·31 per cent. of them were protected, against 63·4 in the preceding year, and 60·8 per cent., the mean of the previous three years. In the municipal towns where vaccination is compulsory, the percentage protected of the estimated number of infants born was 71·37.

About 2·06 per cent. of the primary operations were verified by the Sanitary Commissioner, and 55·6 per cent. by Native Superintendents, the percentages of success found by them being, respectively, 97·4 and 94·6, against 97·1 reported by the vaccinators.

Operations were started by the vaccination with lanoline lymph of children in each municipal town and district; when a good result was obtained calves were inoculated and distributed, one to each vaccinator, throughout the district, where the supply of fresh calf lymph was maintained during the season.

Madras.—The work of vaccination was carried on in Madras under the general supervision of the Sanitary Commissioner, by the Deputy Sanitary Commissioner with the assistance of the District Medical and Sanitary Officers and 61 Deputy Inspectors, with an average staff of 818 operators, or six fewer than in 1897–98. The total number of operations performed by them in 1898–99 was 1,105,084, against 1,258,010 in the previous year, the average number to the credit of each vaccinator falling from 1,508 to 1,330. Excepting the districts of Tanjore, Vizagapatam and Malabar, there was a decrease in all districts, which is attributed to a variety of causes, the more important being the plague inoculation scare, the absence of vaccinators, and the irregular supply of vaccine, to which may be added the absence on other duties of the Deputy Sanitary Commissioner, and the misconduct of not a few of the Deputy Inspectors.

The number of primary operations was 1,028,221, or 148,879 fewer than in the preceding year; and the number of re-vaccinations was 76,863, or 4,047 less than in 1897–98; the percentages of success claimed being, respectively, 89·6 and 75·5, as compared with 92·0 and 81·0 in the preceding year, and 92·6 and 80·2 in 1896–97. The apparent progressive decline in the percentage of success in primary cases is ascribed by the Deputy Sanitary Commissioner to recent figures being probably "a nearer approximation to the truth than those previously recorded."

By the staffs of dispensaries 12,909 operations were performed, or 810 less than in the preceding year. The percentage of success claimed in primary cases was 83·6, practically the same as in 1897–98, but in re-vaccinations it fell from 72·8 to 68·1.

Estimating the number of children born during the year at 40 per 1,000 of the population, the percentage of infants protected was 19·84, compared with 23·23 in 1897–98, and 22·0, the mean of the previous three years.

No inspections were made by the Deputy Sanitary Commissioner as he was engaged during the greater part of the year on duty in connection with plague. The percentage of inspections performed by Civil Surgeons and Native Superintendents, however, rose from 2·5 and 49·7 in 1897–98 to 3·0 and 56·7, the degree of success found by them being 86·0 and 87·7 per cent. of the cases seen against 88·7 claimed by the operators.

No humanized lymph was used, and operations were performed with fresh calf lymph, calf lymph preserved without admixture between glass plates, lanolinated lymph and glycerinated lymph. The following table shows the extent to which the various vaccines were used in the districts, excluding municipalities and dispensaries, and the degree of success obtained with each :—

—	Number of cases, primary operations and re-vaccinations.	Percentage of success.
Fresh lymph	229,439	97·6
Preserved lymph without admixture ...	100,690	95·9
Lanolinated lymph	232,281	88·0
Glycerinated lymph	428,985	82·4

As usual, the best results were obtained with fresh calf lymph ; lymph preserved without admixture comes next, then lanolinated lymph, and lastly glycerinated lymph. The improvement in the results obtained in 1898–99 with the lanolinated lymph, as compared with the previous year when the percentage was 86·6, is ascribed to full instructions regarding its use being issued to vaccinators, while it seems possible that the falling off in success with glycerinated lymph from 88·1 per cent. in 1897–98 was due to an inferior supply being sent out from the Cocanada depôt during a part of the year, but this is not fully brought out in the provincial report.

Coorg.—The vaccination department in the small province of Coorg was supervised by the Civil Surgeon, who had working under him a Native Inspector and eight vaccinators. The total number of operations performed was only 5,283, or rather less than half the total of the previous year. The cause of this extraordinary reduction was a plague inoculation scare excited among the people by the currency of an absurd rumour that anti-plague inoculation was being practised in the guise of vaccination. Of the operations performed, 4,554 were primary and 729 were re-vaccinations, the ratios of success being, respectively, 93·15 and 80·93 per cent. At the dispensaries 390 operations were performed, of which 72·80 per cent. of the 239 primary operations succeeded, and 60·93 of the re-vaccinations.

The percentage of infants protected was smaller than in any year since 1892-93, being only 7·38 of an estimated number equal to 40 per 1,000 of the census population.

The Civil Surgeon himself verified 7·95 per cent. of the operations against only 1·55 per cent. in the previous year, but the percentage verified by the Native Inspectors fell from 31·93 in 1897-98 to 10·95. Calf lymph was used exclusively.

Bombay.—Towards the end of 1898 the Native State of Cambay was "permitted to maintain a complete vaccination organization of its own," and the figures which, however, in 1898-99 relate to only 2,344 operations, have been separated from those of the Presidency proper.

The vaccination staff under the Sanitary Commissioner in Bombay and Sind, excluding Native States maintaining their own agencies, consisted in 1898-99 of five Deputy Sanitary Commissioners, one Superintendent of vaccination in Bombay City, 45 Superintendents of Sanitation and Vaccination, and an average of 434 vaccinators.

The number of operations performed by them was 668,529, or 67,880 less than in the preceding year, excluding the returns for Cambay, while the number of operations performed by each vaccinator fell from 1,690 to 1,539. The decrease occurred in both classes of operations, and was general throughout the Presidency, except in Bombay City, where there was a trifling increase.

In explanation the Sanitary Commissioner writes :—

"As in 1897-98, the year under report was a disastrous one for vaccination work. Firstly, there was during the later months of 1897 and early ones of 1898 a very low birth-rate and a very high death-rate, especially among children; during 1898 the former was very pronounced, and it was not until August that much improvement took place; then, there was still a certain amount of famine in some parts, and some other parts had not completely recovered from it. The plague was with us all the year and greatly interfered with work, so much so in some parts that vaccination had to be entirely stopped; nearly all the Deputy Sanitary Commissioners were on deputation, or leave, or on plague duty, and as no full-time officers were appointed their districts received very little of that inspection and supervision which is so very necessary in order to obtain efficient work; and lastly, several of the inspectors and vaccinators were on plague duty."

Of the total number of operations, 621,097* were primary and 92·86 per cent. of them succeeded, as compared with 91·90 in 1897-98. The number of re-vaccinations was 47·432, of which 56·97 per cent. were successful, as compared with 58·41 in the previous year.

Besides these, 1,915 operations were performed by the staff of dispensaries, of which 953 primary operations and 659 re-vaccinations, or 96·75 and 71·86 per cent. respectively were successful.

Taking the total births at the rate of 40 per 1,000, 49·91 per cent. of the children born were protected, against 55·54 in 1897-98, and 58·11, the mean of the previous three years.

Small-pox was very prevalent in Southern Arabia, and an additional vaccinator was engaged in Aden, while a vaccinator was sent to Lahej at the request of the Sultan of that place. The Arabs in the interior, it appears, are beginning to appreciate the benefit of vaccination, as many came to Aden to be operated upon, giving as their reason that "those who on former visits to Aden had been vaccinated were able to go about among the infected with impunity."

Owing to their absence on other duty but little inspection was done by Deputy Sanitary Commissioners, although that little, 2·32 per cent., was more than in the previous year, 1·18 per cent. Native inspecting officers, moreover, verified 40·68 per cent. of the cases against 31·79 in 1897-98.

Vaccination has hitherto been compulsory in the towns only of Bombay and Karachi, but in December, 1898, the Act was introduced into the town of Larkhana in Sind.

Inoculation was not practised anywhere except in the Nara Taluka of the Khairpur State, and measures have been taken to secure its discontinuance there.

Both humanized and calf lymph were used, the latter in Bombay City and in selected places.

On account of the non-receipt of returns from the Native State of Palanpur and the inclusion in the statistics of those from Cambay, the figures representing the number of operations in the Native States are not comparable with those of 1897-98. In the States of Baroda, Cutch, Kathiawar, Idar and Cambay, there was an aggregate of 192,895 primary vaccinations, of which 95·55 per cent. were successful, as compared with 94·90 per cent. in the preceding year. The number of re-vaccinations was 8,995, and 68·99 succeeded, against 67·22 in 1897-98. Nearly all the operations were performed on children,—153,049 infants were protected, and 30,341 children between one year and six years of age,—the total protection afforded being 28·23 per 1,000 of the population.

Burma.—The staff under the general supervision of the Sanitary Commissioner comprised the District Civil Surgeons, the Municipal Health Officers of Rangoon and Mandalay, and 12 Native Inspectors, with an average number of 177 vaccinators, or 10 more than in the preceding year. The number of operations performed by them was 466,308 against 421,786 in the preceding year, and 414,845 in 1896-97. Both classes of operations increased; the primary numbering 439,050 or 38,732 more than in 1897-98, and the re-vaccinations numbered 27,258 or 5,790 more than in the preceding year; but while the former increased in 30 of the 38 districts the latter increased in only 17.

* The grand total, 668,529, includes 779 secondary operations performed after the failure of the primary operations.

The causes of the improvement were the augmentation of establishment, the extension of the Act to four more municipalities, and the prevalence of small-pox in Rangoon and the districts in its vicinity.

Compulsory vaccination of immigrant coolies in Rangoon was stopped in August 1896, and the question of the introduction of an Act to legalise the compulsory vaccination of all unprotected adults is still pending.

Primary operations succeeded at the rate of 94·71 per cent. and re-vaccinations at the rate of 59·55 against 94·56 and 61·38 per cent. in the preceding year.

Dispensary vaccination continues to increase; the number of cases in 1896-97 was 8,403; in the following year it rose to 9,764, and in 1898-99 it has reached 14,349. Of these operations, 8,209 were primary, and 6,140 were re-vaccinations, the percentages of success reported being 88·66 and 62·70, respectively.

In all, 122,895 infants were protected, equal to 37·71 per 1,000 of the births estimated at 40 per 1,000 of the census population, as compared with 34·34 per cent. protected in 1897-98, and 24·15 per cent., the average of the previous three years.

In the Shan States only primary operations were performed. In the Northern States the number was 2,975 and the percentage of success 82·49; and in the Southern States the operations numbered 3,750, and succeeded at the rate of 86·80 per cent.

The proportions of the operations verified by Civil Surgeons and Native Superintendents were, respectively, 21·67 and 18·14 per cent., as compared with 22·58 and 16·52 per cent. in 1897-98, and they found 89·35 and 89·07 per cent. to have succeeded, against a percentage of 92·66 claimed by the vaccinators.

In Mandalay, Bassein, Moulmein and Akyab, locally prepared calf lymph was used, but the rest of the province obtained prepared vaccine from the depôts at Rangoon and Taunggyi. From the former depôt 16,979 grains of glycerinated lymph were supplied, of which the quality is stated to have been generally excellent. From Taunggyi 17,253 grains of lanolinated lymph were issued; up to the end of 1898 the quality was good, but later supplies were inferior.

Ajmer-Merwara.—In the British Territory of Ajmer-Merwara the work of vaccination was supervised by the Civil Surgeon of Ajmer aided by a Native Superintendent. The number of operators in 1898-99, as in the preceding year, was 13. The number of operations was 17,948, of which all but 132 were primary, as compared with a total of 16,555, including 75 re-vaccinations in 1897-98. The percentage of success reported was 98·46 in primary cases, or slightly less than in the preceding year, when 98·74 per cent. succeeded, but re-vaccinations were more successful, 65·15 per cent. against 61·33.

Estimating the children born at 40 per 1,000 of the population, 55·34 per cent. were protected during the year against 51·3 per cent. in 1897-98, and an average of 46·04 in the three years ending with 1896-97.

The Civil Surgeon inspected 881, and the Native Superintendent 8,225 cases, and found, respectively, 98·59 and 98·84 per cent. successful against 98·21 per cent. reported as successes by the operators.

Civil Sanitary Works.

Bengal.—During the official year 1897–98, the number of municipal towns in Bengal, excluding Calcutta, was raised from 148 to 151 by the constitution as municipalities of the towns of Asansol, Chandpur and Samastipur. The total income, including opening balances which aggregated £2,134 less than in the preceding year, was £284,332 or £5,634 less than in 1896–97, the falling off being much more than accounted for by the smaller opening balance and by a reduction of £16,367 in the amount borrowed. Of the total income 45·75 per cent., about 1 per cent. less than in the previous year, was devoted to sanitation; 9·84 per cent. was spent on roads; 6·60 per cent. on measures for the preservation of the public safety, and 28·39 per cent. on other requirements. The expenditure on water-supply shows a large decrease, from £36,332 in 1896–97 to £17,511, explained by reductions in capital expenditure of sums of £16,267 and £4,800 on account of the water-works at Bhagalpur and Howrah, respectively. The expenditure on conservancy was £70,588, or £9,154 more than in the previous year, the increase being due to precautions taken through fear of plague. The expenditure on drainage was £7,564, or £507 less than in the preceding year; and the expenditure on markets and slaughter-houses was £2,922 or £1,858

more, mainly on account of the construction of a municipal slaughter-house at Narainganj, and of improvements to the bazaar buildings at Darjeeling.

The average proportion of municipal income applied to original sanitary works, which declined from 5·03 per cent. in 1895–96 to 3·70 per cent. in the year following, fell to 3·57 per cent. in 1897–98. In only fifteen towns, including Bhagalpur (18·10), Sirajganj (17·18), and Birnagar (16·40), was more than 10 per cent. of all income spent in this way; and in no less than 41 towns, against 37 and 28 respectively in the two preceding years, nothing whatever was spent. On the other hand, there was again a rise in the proportion of income spent upon annually recurring sanitary works, from 40·20 per cent. in 1896–97 to 41·73 per cent., the proportions shewing the wide range from 70·53 per cent. in Faridpur to 7·93 per cent. in Joynagar, a small municipal town in the 24-Parganas.

The expenditure of public funds on rural sanitation was £21,565 against £26,685 in 1896–97; while private individuals provided £32,388 as compared with £78,138 in the previous year, when it must be remembered the purse strings of the benevolent were loosened in the presence of famine.

The most important sanitary work carried out during the year was the completion of a portion of the Champanagar and Nathnagar extension of the Bhagalpur water-works at a cost of £1,782.

The constitution of the Sanitary Board remained unchanged, and, as in former years, inconvenience arising from the difficulty in arranging for meetings was met by the circulation to the members of papers regarding the cases under consideration. The principal matters considered at the single meeting which was held were—

(1) The Monghyr drainage scheme; and
(2) The supply of filtered water to the towns on the right bank of the Hooghly.

The following are the more important projects for which preliminary estimates were prepared:—

(1) Alternative projects, eight in number, varying in cost from 24 to 35 lakhs of rupees (£160,000 to £233,300), for the supply of filtered water to the municipal towns on the right bank of the Hooghly. These were submitted to Government.
(2) The Patna water-supply. As stated in last year's report, it has been ascertained that an abundant supply of pure water can be obtained from the old bed of the river Sone, and as all the information necessary for the preparation of a scheme was received, the work was taken in hand.

Detailed estimates in connection with the following were prepared:—

(1) The flushing of some of the drains of the Patna Municipality pending the introduction of the water-supply scheme.
(2) The re-modelling of the intake of the Berhampore water-supply works.

Estimates and plans for the following projects were considered:—

(1) A scheme for the drainage of the town of Krishnagar by opening out the Anjana *khal*.
(2) A scheme for the drainage of Monghyr. The Board, while approving of the details of the drainage scheme, were of opinion that the introduction of a supply of water should precede its execution, and recommended the municipality to endeavour to introduce the water-supply scheme in combination with the drainage scheme; but Government, considering that the cost would press heavily upon the poorer tax-payers, have for the present declined to accord administrative sanction.
(3) Extension of the Howrah water-works. Scheme approved by the Board and sanctioned by Government.
(4) Re-excavation of Shiljoorie and Bijapur *khals* in connection with the drainage of the town of Comilla.
(5) Improvement of the drainage of Manicktolla. A surface-drainage scheme estimated to cost £3,330 was referred to the Board for opinion, but in the absence of details regarding levels, etc., had to be returned for re-submission with the necessary information.
(6) Extension of the unfiltered water-supply to the town and suburbs of Calcutta.
(7) Scheme for improving the Darjeeling water-supply system.
(8) Project for the construction of a municipal market at Narayanganj.
(9) Plans and estimates for lining the settling tanks of the Bhagalpur water-works with cement to prevent leakage were rejected, and a less expensive method by the use of fine sand was recommended.

(10) Dacca conservancy scheme. The Municipal Commissioners prepared two schemes—

(*a*) The sewage to be removed by carts from 30 depots to railway sidings and taken thence by rail to trenching grounds three miles away from the town—cost, £3,534.

(*b*) The sewage to be removed by carts to three new trenching grounds to be selected—cost, £2,000.

The Board supported the latter scheme (*b*) to Government.

(11) Drainage of the Siwan municipality.

(12) Remodelling of the intake of the Bhagalpur water-works. The existing intake readily gets choked with sand, and attempts to clear it are unsuccessful owing to the strong current flowing past the mouth of the pipe.

(13) A survey for drainage for the town of Nator was completed.

Numerous miscellaneous references were made by Government and by local authorities; the most important among the former was the question of bringing municipal water-works under effective control, and among the latter the passing of the tenders for the Howrah water-works extension.

In October the Board called for replies to a circular issued during the previous year to municipal committees and local officers regarding experiments on the biological treatment of sewage and waste liquids. From the replies received it seems that in only 30 municipalities were experiments made, but these were mostly successful. In this connection it may be noted that the Sanitary Engineer was placed on temporary duty in England with a view to his making himself acquainted with the more recent methods of sewage disposal. On his return to Bengal he published a brochure* on the recent methods of sewage disposal, which, under the orders of the Board, has been widely distributed in Bengal for the information of those concerned.

Assam.—The total income of the municipalities, stations, unions, and towns in Assam in 1898 was £17,323, as compared with £17,212 in the previous year; and of the total 45·52 per cent. was spent on sanitary works proper, against 43·98 per cent. in 1897. By far the largest percentage of income devoted to sanitation was 72·04 in Tezpur; elsewhere the percentages varied from 59·24 in Gauhati to 22·42 in Jorhat. No work of capital importance was undertaken during the year, nor, as indicated by the Chief Commissioner, is any large undertaking likely for many years to come in the small straggling towns of this province. In Gauhati, although £682 was spent on repairs to the pumping engine and other details connected with the water-works, the water-supply of the town is not yet in a satisfactory state, and the municipality have applied for a loan of £904 for further improvements. The Shillong station water-works suffered severely from the earthquake of 1897, and have not yet been completely repaired; £1,334 are required for the purpose, and steps to obtain funds have been taken. The water-supply of Sylhet was improved by sinking a well, and by the enclosure of tanks with barbed-wire fences. It is reported that the trenching of night-soil is not successful in the towns, as it has not been possible to get the land cropped; but as cultivators for such land can be found elsewhere, it is not clear why they cannot be found in Assam. Meanwhile, the incinerators at Silchar, Manipur, and Aijal are said to have worked well.

The sanitary works carried out in rural areas consisted chiefly in the construction and repair of wells, and the excavation and deepening of tanks. There were 35 Norton tube-wells sunk by the direction of the Barpeta local board and nine at the instance of the Gauhati board.

The use of village sanitary inspection books has been introduced into selected villages in each district, but so far with very little practical benefit.

No meeting of the Sanitary Board was held during the year, but the written opinions of the members were obtained on all sanitary questions of importance which were being considered.

North-Western Provinces and Oudh.—The constitution during the official year 1897-98 as a municipality of the town of Haldwani, in the Naini Tal district, raised the number of municipal towns to 104. Excluding opening balances, the total of the municipal income was £298,878, as compared with £276,859 in the preceding year. Except under the head of conservancy, upon which the sum expended rose from £62,562 to

* "Recent methods of sewage disposal in England, by A. E. Silk."

£66,009, there was a general reduction of the sums devoted to sanitary works; the expenditure on water-supply fell from £59,368 to £35,216; on drainage from £21,008 to £12,073, and on markets and slaughter-houses from £2,389 to £1,869; the aggregate expenditure reaching £115,165.

Except the further extension of the Allahabad water-supply to Karela Bagh, the remodelling of the Naini Tal water-supply and the completion of the Bhilaru sewage shoot at Mussoorie, no large work of importance was begun or completed, and the following notes have reference mainly to important works in operation, or in progress of completion.

At Agra, the daily average consumption of filtered water rose from 1,338,177 gallons in 1897-98 to 1,519,678 gallons, or 8·96 gallons per head of the population. In the cantonment the average daily consumption fell from 185,718 to 164,013 gallons. The additional filter, to the necessity for which allusion was made in last year's report, has not yet been supplied owing to financial difficulties, and, in the meantime, the total daily output of filtered water has been limited to $1\frac{1}{2}$ million gallons.

At Allahabad, the average daily consumption of filtered water was 1,410,229 gallons, equal to 8·04 gallons per head of the population. Improvements were effected at the intake which have removed the fear of the water-supply being diminished owing to the falling of the river in the hot weather, and have improved the quality of the water in the inlet well.

At Benares, there was an increase of $22\frac{1}{2}$ per cent. in the quantity of filtered water consumed, from an average of 1,905,216 gallons per diem to 2,336,084, or 11·04 gallons a head. The raised reservoir was completed during the year.

At Cawnpore, the daily average consumption of filtered water rose from 1,325,409 to 1,431,901 gallons, equal to $8\frac{3}{4}$ gallons a head.

At Lucknow, the average daily consumption in the city, civil lines, and cantonments was 978,982 gallons, or 3·7 gallons per head of the population; the maximum supplied in any one day being 6·2 gallons per head. In addition to the filtered supply, about 73 million gallons of unfiltered water were supplied to the Victoria Parks, for which it has been decided to have separate pumping machinery.

At Meerut, the average daily consumption was 406,235 gallons, or 3·4 gallons per head of the census population, but 6·2 gallons per head of the population reached by the supply.

At Mussoorie, the consumption of pumped water during the year was about 4,973,000 gallons.

At Naini Tal, the total quantity of water pumped was 10,681,500 gallons; but in addition to this the new springs tapped under the remodelling scheme yielded 6,000,000 gallons, and saved the cost of pumping for three months, while Rosamond's well springs yielded 2,102,500 gallons, and the gravity service to the Mall and Lower Bazar, 1,314,000 gallons. Thus, the total quantity distributed by pipes was nearly 32,000,000 gallons, or $8\frac{3}{4}$ gallons per head of the average population of 10,000.

An estimate, amounting to £17,000, for extending and remodelling the water-supply system was sanctioned in March, 1898; the pipes began to arrive in November, and before the end of the year were nearly all laid. The engines and boilers arrived in February, and though delay occurred, owing to parts of the boiler having been sent out incomplete, their erection was nearly finished by the end of the year.

At Rajpur and Dehra, the springs supplying the towns by gravitation yielded a good supply throughout the year, but no record of the quantity was maintained.

The water supplied to the towns was regularly analysed and generally found to be of excellent quality. At Agra, however, microbes resembling those associated with the causation of enteric fever were detected, and measures were taken to remove the defects which were supposed to lead to their presence in the water.

Less than half a lakh of rupees (about £3,330) was spent on the Benares sewage works during the year. Tenders were invited for the construction of sewers in the unsewered area, but the rates offered by the single firm that tendered were prohibitive, so it was decided to carry out the work departmentally. Subsequently, in accordance with the wishes of Government, it was decided to leave the unsewered area and deal first with the populous sewered area along the bank of the river. The design and details of the work gave rise to a good deal of discussion, and the project was not sanctioned until September, after which the plans and fittings had to be procured. This, and the difficulty in obtaining a supervising staff of sufficient experience, account for the small sum spent during the year.

The Bhilaru sewage shoot at Mussoorie was completed in July, 1898 ; but as the road from the bullock depot to the intake tank was not completed, the shoot was not used until October.

Surveys, with a view to introducing proper systems of surface drainage, were in progress or completed in the towns of Hathras, Aligarh, Fyzabad and Jhansi.

The Sanitary Board met three times at Naini Tal during the recess, and the following were the more important matters which engaged their attention :—

(1) The reports by the Sanitary Engineer on the quality of the municipal water-supplies. It was noted with satisfaction that the supplies were generally pure, and that the large reduction effected in the quantity of organic matter showed that careful attention had been paid to the filters. The board recommended that monthly qualitative bacteriological examinations should be made of the filtered water, and this recommendation has been accepted by Government.

(2) The sanitary condition of the town of Baghpat. The measures of improvement recommended by the Sanitary Commissioner and Sanitary Engineer were considered, and it was recognised that the finances of the municipality did not at present permit of any extensive drainage or water-supply scheme being carried out. Any funds the municipality can spare are to be devoted to improving the drainage and the sanitary condition of the town.

(3) The question of additional clerical establishment for Civil Surgeons was again discussed, and, after correspondence with Government, an extra clerk was sanctioned for the offices of Civil Surgeons at five of the larger towns.

(4) The reports on the working of the Village Sanitation Act were read, and it was noted that special attention was being given to the protection of the wells from contamination.

(5) A report by the Sanitary Engineer on a water-supply scheme for Jhansi was considered ; and it was agreed that although a supply from the river Betwa would be the best, and will perhaps ultimately be obtained, in the present state of the town's funds the proposed scheme to pump water from the existing cluster of wells would provide a safe and satisfactory supply.

(6) The insanitary state of the town of Kosi was discussed. The town was visited by the Deputy Sanitary Commissioner, and some of the remedies suggested by him having been adopted, there had been a satisfactory decline in the death-rate. The subsoil water of the town is very high, owing to the proximity of the Agra canal and of tanks which have no outlet for storm water ; but a drainage scheme to relieve the country in the neighbourhood of Kosi is being considered by Government.

Punjab.—The total income of the 31 municipal towns in the Punjab was, including the opening credit balance of nearly ten lakhs of rupees, £368,806, as compared with £353,064 in 1897. In spite of an increase to their funds, however, the aggregate expenditure on sanitation under all the most important heads declined ; the sum spent on water-supply was only £11,060, against £14,479 in the previous year ; the expenditure on sewerage and drainage fell from £6,857 to £6,463 ; and the expenditure on conservancy from £42,354 to £39,386 ; the total of all sanitary charges amounting to only £75,007, against £77,860 in the preceding year, and £82,446 in 1896.

The sum realized from the sale of street sweepings and manure, which in 1897 was £9,942, or about £867 more than in 1896, fell slightly in 1898, to £9,900 ; but a decline in the direct profit from this source is not to be regretted if, as in this case, it results from a safer method of filth disposal.

The principal sanitary works completed, in progress, or under consideration were the following :—At Simla, extensive improvements to the water-supply were in progress, some portions of the work being completed during the year. At Haripur, the water-supply project was completed at a total cost of £3,084. At Ludhiana, successful boring operations were carried out at the site where it is proposed to sink wells for the water-supply, the water found was of good quality, and an estimate for the construction of an experimental well was prepared. At Amritsar, the survey and preliminary operations in connection with the new water-supply of the town were completed.

At Lahore, the sewerage and drainage scheme for the city was in progress, as well as work on the Anarkali and Mozung outfall ; but the sewerage and drainage project for Anarkali was deferred for want of funds. At Multan and Rawalpindi beginnings have been made with drainage schemes ; but the drainage projects for Ferozepore City, Fazilka,

Jagraon, and Muktsar remained in the consultative stage, at least no money was spent on them, while the project for the diversion of the town drainage at Abbottabad was held in abeyance.

The sewerage farm in the neighbourhood of Delhi continues to be worked satisfactorily, in so far that the filth from eleven wards of the city is disposed of without nuisance, and the land is let out at a higher rate than was formerly the case.

Little progress is reported in the improvement of rural sanitation ; but efforts are being made to stimulate the interest of the rural population in the subject by the offer of rewards to the village in each tahsil which effects the most improvement in its sanitary condition, the point upon which stress is to be laid to be determined by the Sanitary Commissioner aided by the suggestions of the District Civil Surgeon.

No meeting of the Sanitary Board took place during the year, the reason given being that the members, feeling that the Board had no executive power, would meet uselessly. The question of extending the scope of the Board's work is being considered by the Local Government. During the year, papers relating to subjects of more or less importance connected with sanitation were circulated among the members.

Central Provinces.—The income of the nineteen *sadar* towns in the Central Provinces, which had fallen to £94,024 in 1897, recovered slightly to £95,467 in 1898; and the total expenditure on sanitation rose from £19,204 in the former year to £20,882 in the latter, including £5,275 on water-supply, against £4,096 in 1897, and £13,992 on conservancy, as compared with £13,580.

No new work of any magnitude was begun during the year ; but the water-supply works at Jubbulpore and Wardha were completed at a cost, respectively, of £16,512 and £14,876.

At Khandwa, further progress on the water-supply works was made ; and at Bhandara the works were completed, with the exception of the laying of the distribution pipes. At Harda, the water-supply project remains in abeyance apparently for want of funds.

The sum allotted for village sanitation was £6,428 ; but only £2,366 was spent, including £878 on the construction of wells, mostly in the districts of Sambulpur, Wardha, and Nagpur, and £67 on the construction of tanks in the Nagpur district. On site cleansing, £1,086 was spent, and on drainage and roads, £153.

Progress continues to be made in the record of sanitary progress in the villages ; and new sanitary maps, with lists of the villages included in them, have been prepared in order to start a new system of registration.

The constitution of the Sanitary Board remained unchanged, and a meeting was held at each divisional headquarters. As in former years, the principal business was the improvement of sanitary conditions in villages.

Berar.—The estimated income of the twelve municipal towns in Berar, in 1898, was £17,702, or about £134 less than in the previous year ; and the actual expenditure on sanitation was £8,984, as compared with £11,278. The decrease was distributed under all the principal headings ; the expenditure on water-supplies falling from £3,860 to £2,898 ; on conservancy, from £4,457 to £4,210 ; on drainage, from £706 to £196 ; and on miscellaneous works, from £2,254 to £1,682. The apparent falling off in the expenditure on drainage is greater, while that on conservancy is less, owing to the Sanitary Commissioner having transferred certain sums, formerly reckoned under the heading drainage, to the heading conservancy.

No new work of considerable magnitude was undertaken during the year.

The expenditure under the heading water-supply represents for the most part the repayment of loans ; but there was a great deal spent on pumping. Unfortunately the water-supply works at Akola and Amraoti have disappointed the expectations formed of their performances. At Akola, the failure of the rains and the great heat so lowered the water level in the wells at Kapsi and Majode that pumping had to be carried on for a longer time than usual, under unfavourable circumstances, and, unhappily, at an exceptionally high cost. At Amraoti, the Kalapani tank dried up, but fortunately a fairly good supply of water was discovered by Dr. Khote at the confluence of two nullahs near Rajapeth, where a well was sunk and water pumped for the supply of the town.

At most of the towns night-soil is trenched, but the trenches are not in all cases cropped. Street sweepings and household refuse are generally sold to contractors for brickmaking.

In the districts, the sum devoted to sanitation fell from £7,032 in 1897 to £5,170 in 1898, including £1,944 on water-supplies, and £2,600 on conservancy.

Village sanitary inspection books have been introduced in five selected villages in each district. The books are kept up by *taluka* officers not below the status of *tahsildar*, and are sent annually to the Civil Surgeon's Office, there transcribed, and returned to the village official. "The information so recorded," it is stated, "will be put to some practical use in future."

No information is given by the Sanitary Commissioner about the proceedings of the Sanitary Board.

Madras.—Excluding the presidency town, the estimated income of the fifty-eight municipal towns in Madras, in the official year 1898–99, was £197,082, as compared with £215,208 in the preceding year. The allotment for sanitary purposes was £104,770, or 53·2 per cent. of the total, against 63·6 per cent. in 1897–98. The actual sums expended during the nine months ending with December, 1898, were, except in the case of conservancy, much less than in the corresponding period in 1897; on water-supply, only £8,022, against £27,140; on the improvement of sites, £10,136, against £10,890; on miscellaneous sanitary improvements, including the repair of tanks, £3,912, against £5,282; but on conservancy, the sum rose from £30,924 to £33,212. The decline in expenditure is explained by the husbanding, by municipal bodies, of their resources against a possible invasion of plague.

The municipal income of the city of Madras was £89,877, or about £6,500 less than in the preceding year, but £56,299 was set aside for sanitary purposes. The actual expenditure during the first nine months of the official year was £35,964, as compared with £30,356 in the corresponding period in 1897. The bulk of the expenditure was on conservancy, £19,734, and on miscellaneous improvements, £9,908, as compared with sums of £15,872 and £11,246 respectively in 1897. On water-supplies, the expenditure in 1898 was £887, against £194, and on site improvement £3,530, against £2,419.

At Conjeeveram, the construction of additional works, viz., the fencing in of the pumping station, the construction of a service reservoir, and the extension of the pipe service were nearly completed, the cost being met from savings effected on the original estimate for the water-supply works.

Surveys in connection with water-supply schemes were made at Berhampur, Bezwada, Chidambaram, Guntur, and Kumbakonam; and five water-supply projects for Bezwada, Kurnool (extension), Tanjore (extension), Tiruvannamalai, and Vizianagram, and one drainage project, Kumbakonam, were prepared and submitted either to Government or to the Sanitary Board.

At Bezwada, it is proposed to sink three infiltration wells in the bank of the Kistna, and to pump water from them through a twelve-inch main to a service reservoir situated on the highest land between the pumping station and the town, the water being distributed by gravitation to fountains in the town. The scheme will give 15 gallons per head daily to an estimated population of 30,000, and will cost £25,027.

At Kurnool, after the completion of the water-works, there remained a balance of nearly £400, which it is proposed to devote to an extension of the pipe supply.

At Tanjore, it is proposed to extend the works, at a cost of £1,800.

At Vizianagram, the proposal is to cut an infiltration gallery 1,700 feet long, parallel to, and about 1,000 feet from, the bank of the Ootaigedda, a perennial stream about a mile and a half to the north of the town. The water will be pumped from the gallery to a service reservoir at a sufficient elevation on an adjoining hill, and will thence be distributed in pipes by gravitation. The project provides for 15 gallons *per diem* per head to a population of 40,000, and is estimated to cost £18,800.

There has been no advance made in sewage farming, which was carried on at Madras, Erode, Tanjore, Anakapalle, and Vizagapatam. A plot of land was purchased for the purpose at Tinnevelly, but nothing further was done. The income derived from the sale of street sweepings, &c., continues to increase.

The estimated income of the district boards in 1897-98 was £530,847, and the sanitary allotment was 8·3 per cent. of the total, against 8·4 per cent. in each of the two preceding years. During the first nine months of the financial year £24,656 were spent, including £3,704 on water-supplies and £16,611 on conservancy. These sums show a considerable decline as compared with the previous year, due, it is stated, to routine sanitary improvements being put off on account of the demand for funds to meet the possible occurrence of plague.

Little progress, it seems, has been made in ordinary rural sanitation, but the Sanitary Commissioner has great hopes of the results of a revision of the Act for Local Fund areas, which is being made.

The constitution of the Sanitary Board remained unchanged, but the rules for the conduct of business were slightly modified by the addition of a rule making it incumbent on collectors to consult the Board when special difficulties, for which rules do not provide, arise in the laying out of house sites near railway stations. The Board scrutinised plans and estimates for 36 municipal and 78 local fund works, estimated to cost in the aggregate £32,636. Besides examining the various projects of which mention has already been made, proposals in connection with many other schemes, for which estimates had not been prepared, were considered by the Board.

Coorg.—The total expenditure on sanitary works in the small province of Coorg in 1898 appears to have been less than one hundred pounds, devoted chiefly to the construction of a new well at Gonikoppal, and to an improvement of tanks and of drains at Somwarpett.

The Sanitary Board met three times during the year, and the following was the principal business before them :—

(1) A suggestion made by the Civil Surgeon that each municipality should entertain one or two Sanitary Inspectors was considered a good one, and it was agreed that it should be brought before the town committees, but it was pointed out that as the towns are very poor it was doubtful if the necessary funds could be provided.

(2) The prevention of the invasion of plague from the neighbouring province of Mysore. The measures recommended were strengthening the medical inspecting staff, and strict attention to the sanitary condition of towns, villages, and coolie lines. Measures were adopted for the engagement of a plague supervisor and five plague inspectors, and a simple set of instructions for disinfection was drawn up and copies circulated among the inhabitants.

(3) A plan for a hospital at Pollibetta was approved.
